Short way	Decreases proportionally the green interval for each phase by a predetermined time prior and cycles through the signal timing plan until the coordination or offset point is reached; this process is repeated with the decreased cycle length until this offset point is achieved		Obenberger and Collura (2007)
Fixed exit phase control	Traffic controllers can select only one set of exit phases after emergency pre-emption	ASC/3-2100	Yun et al. (2011)
Dynamic exit phase control	The exit phases can be changed dynamically after the EVP operation according to the location of the EVP call within the local cycle timer using the programming function available in advanced traffic controllers	ASC/3-2100	Yun et al. (2011)

EVP State of the Art

A fair amount of new theoretical approaches are proposed in the literature to improve the basic concept of EVP presented in Fig. 1 such as route-based dynamic preemption. Summary of such studies is presented below.

Multiple Preemption Requests

Head et al. (2006) presented that in case of multiple priority requests at an intersection, first-come, first-served policy results in a higher total delay to the vehicles receiving priority than would result, if no attempt to provide priority were made at all. Head et al. (2006) and He et al. (2011) proposed an analytical formulation to best serve multiple priority requests by deciding phase times for each cycle and by allocating different priority request to different signal cycles, respectively. Both these studies aimed at minimizing the total priority delay and do not guarantee the highest priority vehicle to be served first. Thus, Asaduzzaman and Vidyasankar (2017) proposed to first sort multiple conflicting EVP requests based on their priority weight and higher priority requests get the schedule first.

Route-Based Strategy

Most of the state of practice EVP systems operate on a single-intersection basis and depend on of the EV at each intersection—also referred to as the local detection—to activate preemption request at each intersection. However, on a saturated or oversaturated network, after locally detecting an EV approaching the intersection, there may not be enough time available to clear the intersection for an EV to pass without stopping or reducing its speed and this results in a delay at intersections.

For avoiding such situations and improving the efficiency of EVP system, Kwon and Kim (2003) and Gedawy et al. (2008) proposed a route-based signal preemption method that identifies an optimal route for an EV in real-time and clears intersections on a designated EV route. The data from the loop detectors are used to quantify the travel cost of each link through time and to find minimum-cost-path. These studies assumed the existence of a reliable congestion detection system that can measure the congestion level on the roads of the network and report it to the central server. However, practicality and reliability of congestion detection system and eventually route-based EVP system has not been tested on the field.

Once the optimum route is known, Mu et al. (2018) proposed to use a multi-objective programming model to obtain phase durations at each intersection along the route. The objectives can be the minimal residence time of EV at all intersections and the maximal passing numbers of general vehicles. Researchers like He et al. (2014); Kang et al. (2014) suggest that providing maintaining coordination among signalized intersections along EV's route can improve the travel time of EV.

Contrary to predetermining EV's route, Kamalanathsharma and Hancock (2010) proposed sequential preemption, that is, when the EV enters the corridor, it is detected, and preemption is requested to the first intersection controller which then transmits the request to downstream controllers. Using real-time or historic queue measurements, preemption offset for each intersection on response route is calculated and sequential preemption is set to provide an uninterrupted way to EV. Similar logic has been implemented in STREAMS EVP system (Transmax, 2018).

Research also suggests that the emergence of connected vehicle (CV) technologies such as vehicle to vehicle (V2V) and vehicle to infrastructure (V2I) communication can also benefit the EVP operations. For example, Noori et al. (2016) proposed an EVP strategy considering V2I communication is available in EV as well as in all passenger cars on the road. For a given route of EV the proposed strategy considers all traffic signals along the EV route, and finds the number of vehicles stopped at each traffic signal, and based on these number, changes the signal status to provide early green before the EV reaches the signal. Noori et al. (2016) proposed preemption strategy showed a significant reduction in EV's travel time when evaluated in a large-scale realistic simulation environment.

Other than the aforementioned research on various aspect of EVP, some of the researchers have also focused on evaluating the performance of EVP operation. Hanbali and Fornal (2004) assessed the performance of the EVP system operating in the city of Milwaukee, US, that is, OPTICOM emergency response by Global Traffic Technologies LLC. (2020). Though the study found that the optimal priority control efficiently serves the need of EV minimizing the disruption to other traffic on the road, several constraints exist while implementing the optimal priority control strategy that is unique to each intersection depending on the geometry. For instance, the existence of lift bridge, unusual pedestrian phasing, etc. Teng et al. (2012) used GPS data from fixed-route transit vehicles in the Las Vegas area to evaluate the impact of EVs on arterial traffic speeds. The results indicate that speed variance is significantly higher during EVP and the mean speeds of traffic flowing in the same direction as the emergency vehicle and on crossing streets are lower during preemption than during normal conditions. Moreover, signal preemption during peak periods and duration of pre-emption had a significant negative impact on traffic speeds. Also, the transition time has a negative impact on traffic speeds.

Conclusion

Emergency vehicle pre-emption algorithm is used to give EV a priority green light at an intersection. The three critical goals of EVP operation are to reduce EV's response time, ensure the safety of EV as well as other vehicles on the road and minimize interruption to normal traffic on the road. EVP operation includes three major steps, namely, detection of EV, the transition of traffic signal into

preemption and out of preemption. EVP technology has been deployed in various developed countries that have appropriate infrastructure such as infrared signals for communication between EV and signal control, AVL systems in EVs. Evaluation of EVP systems at a various location has shown a significant reduction in travel time of EV.

Research has been conducted to further improve performance of EVP systems such as optimally serving multiple EVP requests at an intersection, avoid EVs getting caught behind the queued vehicles at an intersection due to failing to clear queues at the intersection before EV's arrival. Research suggests optimizing the allocation of priority requests in case of multiple requests instead of serving on first come first basis. Researchers have also suggested applying EVP strategies to route instead of detecting EV and using EVP strategy at each intersection individually. However, these advancements in EVP operation and corresponding improvements lacks real-world validation. Also, interruption to general traffic due to EVP and its impact on the performance of the road network is rarely evaluated. Consequently, further research is required to improve the strategies for transition out of pre-emption which can lead to minimum interruption to general traffic. Lastly, the impact of EVP on the safety of EV as well as other vehicles on the road network needs more attention.

Introduction

Traffic congestion and environmental pollution are among the most common problems that are encountered in many cities in the world. To minimize the negative effects of these problems, different types of traffic management approaches have been taken into account for many years. Roundabouts are one of the intersection types used for these purposes. The priority control approach is the main idea of traditional roundabouts. However, traditional roundabouts are suitable for low-traffic volumes. When traffic volume increases and flow is unbalanced, a roundabout cannot automatically adjust to meet traffic demand and queue length and delays are greatly increased and even the junction can be locked (Guo and Lin, 2011). Unbalanced traffic flow problem is one of the most important problems for roundabouts and needs some additional control application such as metering signals, etc. Unbalanced traffic flow conditions are observed when the traffic volume values in the junction entrance are very different from each other (Akcelik et al., 1996, 1997, 1999). In several countries, including China, United Kingdom, France, Sweden, Australia, Netherlands, and Turkey, some roundabouts have signal control, especially where the vehicle and pedestrian traffic are heavy and unbalanced. This application can be defined as a combination of signalized intersections and roundabouts (Murat et al., 2019).

Signalized roundabouts are used in cases of an increase in demand for traffic flows or violation of traffic rules by drivers in general. In the first case, because of an increase in demand on some arms (unbalanced flow), the capacity of the intersection may decrease dramatically and excessive delays may occur. Vehicle delays can be decreased and traffic safety can be improved by the use of signalized roundabouts (Pilkko et al., 2017). Another main reason to use signalized roundabouts is related to driver behavior at roundabouts without signals. In some developing countries, drivers are not accustomed to roundabouts and often violate the traffic rules. Because of this violation, bottlenecks occur. The bottlenecks of a roundabout with two or more circulatory lanes are the weaving sections, where the vehicles enter or leave the roundabout. Thus, signal control is integrated to prevent possible traffic accidents and increase intersection capacity.

Signalized roundabouts have been used in the world since the 1950s. The use of signal control and design procedure for roundabouts is somewhat different for the countries.

In Europe, the use of signalized roundabouts is common. However, design criteria and reasons for use are different. In the United Kingdom, the design criteria of signal-controlled roundabouts have been summarized in a document as a series of local transportation notes (TSO, 2009). In this note, the first implementation is stated in 1959 for the UK. The reasons for the use of signal control for roundabouts are investigated and the safety issue for both the pedestrians/cyclists and the cars are stated as one of the main reason in this document. Partial control of a roundabout is often employed where delays do not occur on all arms. It is also stated that, in some cases, signal control is used a part-time basis in the UK (TSO, 2009).

The capacity and traffic safety issues are the main reasons for traffic signal implementation on roundabouts in the Netherlands (DHV, 2009). Some reasons include:

- The insufficient overall capacity of the roundabout;
- Heavy left-turning traffic flow;
- Unacceptable delays and/or queues on one or more of the connecting legs.

Sometimes the problems to be solved are (also) traffic safety-related:

- Due to high-circulating speeds drivers experience difficulties when merging with the traffic on the multilane roundabout;
- For pedestrians and cyclists, it is difficult to cross the multilane legs of the roundabout.

In the Netherlands, the implementation of a traffic signal on roundabouts is classified into four categories:

1. Traffic signals meter traffic on one or more entries;
2. Traffic signals control entries and exits for the benefit of crossing pedestrians and cyclists;
3. Traffic signals control both the entries and the circulating lanes;
4. Traffic signals on a turbo roundabout

Two-phase control is generally preferred to provide alternating green waves for east-west and north-south through traffic. In the case of heavy left-turn movements, four-phase control is used.

The use of roundabouts is common in France. There are now more than 25,000 roundabouts in France (Guichet, 2005). The French policy is to favor roundabouts over signalized intersections. The French guidelines for the design of urban intersections allow for signalization of roundabouts for pedestrian safety.

In the United States, signalization of roundabouts is discouraged. The roundabout informational guide of Federal Highway Administration states “roundabouts should never be planned for metering or signalization.” (FHWA, 2000). However, the guide does concede that “unexpected demand” may require signalization after a roundabout is constructed. The FHWA guide goes on to describe three signalization alternatives to be considered: (1) metering, (2) nearby pedestrian signals, and (3) full signalization of the circulatory roadway. In addition to the three warrants for signalization suggested in the roundabout information guide, the guide also points out that signals may be used where “disabled pedestrians and/or school children are present at high volume” (FHWA, 2000).

In China and Turkey, signalized roundabouts are quite common and are familiar to drivers. For both countries, the reasons for using signalized roundabouts can be expressed as traffic safety and congestion problems in general. The problem of traffic congestion and junction gridlock may be observed when drivers violate the priority rule at the roundabout during peak hours. However, traffic accidents sometimes occur due to a violation of the rule. Signalized roundabouts are used as solutions to both problems. Generally, full signaling is preferred.

Types of Signalized Roundabouts

Roundabouts by priority control are self-organized intersections. The signs at the intersection indicate that vehicles entering the roundabout need to decelerate and circulatory vehicles already on the circulatory lanes have priority. Although yield control of entries is the default at roundabouts, traffic flows at roundabouts have been signalized by metering one or more entries, or signalizing the circulatory lane at each entry when necessary. Especially with the increase in traffic volume, priority-controlled roundabouts tend to be congested and difficult to meet the high traffic demand. The use of a signal system for roundabouts may be classified in many ways. In some applications, it is only used for pedestrians (Azhar and Svante, 2011). On the other hand, vehicle traffic is targeted in many applications. Types of signalized roundabouts are examined in the following Fig. 1

Entrance Metering at Roundabouts

Metering signals is one of the applications of signalized roundabouts. Roundabout metering signals help to create gaps in the circulating stream to solve the problem of excessive queuing and delays caused by unbalanced flow patterns and high-demand flow levels. (Akcelik, 2005)

Figure 1 Sample signalized roundabout from Denizli, Turkey. Source: Google Earth, 2015.

Figure 2 Entrance metering at roundabouts.

When low capacity conditions occur during peak periods, for example, due to unbalanced flow patterns, the use of metering signals is a cost-effective measure to avoid the need for a fully signalized intersection treatment. Roundabout metering signals are often installed on selected roundabout approaches and used on a part-time basis since they are required only when heavy demand conditions occur during peak periods. The concept of metering at roundabouts is similar to ramp metering on freeways. In general, signal light and queue detectors are set on two adjacent entrances, which named as metered approach and controlling approach (Akcelik, 2006). The entrance metering at roundabouts is depicted in Fig. 2.

When the queue on the controlling approach extends back to the queue detector, the signals on the metered approach display red to create a gap in the circulating flow. This helps the traffic flows on the controlling approach to enter the roundabout. When the red display is terminated on the metered approach, the roundabout reverts to normal operation (Akcelik, 2011).

Metering signals have been used in Australia, United Kingdom, and United States to alleviate the problem of excessive delay and queuing by creating gaps in the circulating stream. The necessity and effectiveness of the application of roundabout metering are considered in the literature (Natalizio, 2006, Brabender and Vereeck, 2007). In these studies, it is concluded that roundabouts are an important option to reduce traffic accidents and the reduction of traffic accidents is closely related to speed limits at main roads and bypass roads. It is also stated that signalized roundabouts are the safest type of intersection.

Nearby Vehicular and Pedestrian Signals

Another method of metering (refer to Robinson et al., 2000) is the use of a nearby upstream signalized intersection or a signalized pedestrian crossing on the subject approach road. Unlike entry metering, such controls may stop vehicles from entering and leaving the roundabout, so expected queue lengths on the roundabout exits between the metering signal and the circulatory lane should be compared with the proposed queue space (FHWA, 2000). Sample application is shown in Fig. 3.

Entrance Signalization

In this application, traffic flows on each entrance are controlled by a single phase. All vehicles on each entrance are released simultaneously. There is no conflicting traffic flows in this control method. The green light duration can be set according to the traffic volumes of each entrance. It is possible to better balance the traffic flow.

A four-phase release mode is used in entrance signalization generally to minimize the loss at the four-entrance roundabouts. The phase diagram is shown in Fig. 4.

Full Signalization of the Circulatory Lane

In the case of full application, traffic signals implemented on all arms of the roundabout and around the main circle.

Figure 3 Nearby pedestrian signal at roundabout.

Full signalization including control of circulating traffic is possible at large-diameter multilane roundabouts that have adequate storage space on the circulatory lanes. The full signalized control eliminates all conflict points and weaving sections and adapts to roundabouts with two or more circulatory lanes.

Generally, it is used in the cases of an increase in demand for traffic flows, violation of traffic rules by drivers and traffic safety for pedestrians. In the second case, because of the violation of traffic rules by drivers, grid-lock is occurred, the capacity of intersection may decrease dramatically and excessive delays may occur. Besides violation of traffic rules, left-turning volumes, and traffic composition (heavy vehicle rate) have an adverse effect on the capacity of signalized roundabouts. To overcome these deficiencies, a proper signal timing design should be needed. On the other hand, storage area of the central island should be determined appropriately for traffic volumes of left turn vehicles. The storage area is defined as the space that is determined regarding geometric dimensions of the left turn lanes around the central island. In [Figure 5](#), a sample application and storage area are shown.

In the field, different control types may be used for full signalization of roundabout. The full signalization may be used in the rush time of the morning and evening periods. The signal light may be turned off in the off-peak period and priority control may be applied to improve the LOS. However, the partial signalization at roundabouts will probably increase potential safety problems.

(Continued)

(Continued)

(Continued)

Figure 5 Full application of signalized roundabout.

The Design Parameters

In the design and operation stages of signalized roundabouts, certain parameters should be taken into consideration. These parameters may be summarized as follows:

- Geometric elements
- Traffic volume of left-turning vehicles
- Storage area of the central island for left-turn vehicles
- Signal timing and phase plan

In the design stage, the parameters stated above should be regarded in detail by field observations. Otherwise, the designer has to make some assumptions about the values of these parameters. In this case, the values assumed might not be compatible with those obtained from the field, which can result in an improper design. In the following, the parameters listed above are examined and discussed.

Geometric Elements

Geometric elements of a roundabout have a significant effect on design. The geometric elements or components such as turning radius, lane width, the radius of the central island, etc., should meet the required standards. The design of an intersection may have some faults when using non-standardized elements. On the other hand, the intersection may operate below capacity because of these design faults. Many studies in literature support these findings. An investigation about the effects of the diameter of signalized roundabouts and the cycle time on vehicle delay revealed that the increased radius of the central island leads to the rise of average delay.

Storage Area of Central Island for Left Turn Vehicles

The storage area of the central island for left-turning vehicles is shown in Fig. 5 and defined in Section Full Signalization of the Circulatory Lane. This area should have some specifications to serve the traffic flows with minimum effects. The number of circulation lanes and the dimensions of the circulation lanes is the main elements to consider. The designer should consider these elements and collect the required data from the field, such as the dimensions of the space for left-turning traffic flows.

Traffic Volume of Left-Turning Vehicles

The left-turning traffic volumes have some considerable effects on the design of signalized roundabouts. The number of vehicles and traffic composition should be observed for a proper design. The signal timing for circulating flows should be determined based on

the traffic volumes and especially the percentage of heavy vehicle. On the other hand, the variations of traffic volumes should also be observed both in peak and off-peak periods and the trend of this variation should be obtained. Otherwise, signal timing assigned may not be sufficient for the traffic volumes and some vehicles may have additional delays. Moreover, traffic jams may also occur because of this improper signal timing design.

The left-turn heavy traffic volumes should be taken into account carefully. The intersection may be congested if the percentage of heavy vehicles is higher than expected. On the other hand, because of the heavy vehicles, the departure headways of vehicles may be affected and grid-lock may be occurred (Nikitin et al., 2017; Murat et al., 2019). The observations and estimations of heavy vehicles should be done well in the design stage.

Signal Timing and Phase plan

The signal timing assignment and phase plan selection has a great impact on the performance of the intersection control system. Although much software for the simulation and design of intersections is developed, signal timings of signalized roundabouts are limited. On the other hand, some microsimulation software may be used only for performance analysis, not for signal timing design. Therefore, signal timing design is a challenge for designers and it may be varied based on the designer's ability and foresight.

Signalized roundabouts are generally controlled by two, three, or four-phased plans. Two-phased management is preferred when the left-turn flows are not significant. Three-phased management is generally used at the intersection of secondary roads and main roads. The phase plans have a considerable effect on the performance of signal control systems. It may be determined by field observations and some specific analysis. Left turning flows, pedestrians, and traffic composition (heavy vehicle rates) are some important parameters that should be considered in phase plan selection. Any negligence of these parameters may lead to unexpected performance results. Thus, design engineers need certain information or a guide to develop more sustainable solutions for roundabouts with signals.

Design Methods

The design of signalized roundabouts generally needs experience in traffic management. In the design, some software such as SIDRA Intersection, TRANSYT, ARCADY, VISSIM, LinSig, etc. may be helpful. In the past, approaches developed for conventional signalized junctions have been used to control signalized roundabouts. In this context, two-phase management and four-phase management have been adopted more. Two-phase management is preferred in the case of low left-turn traffic flows; if left-turn flows increase, four-phase management is preferred. In some cases where conventional design approaches are not appropriate, new approaches are needed. The change in left-turn traffic flows during the day or the traffic safety problems in the weaving areas can be stated as the main reasons for the need for new management approaches. However, the design procedure including signal timing is not properly defined in the literature. In some limited researches, this issue is taken into consideration and design methods are proposed. Yang et al., 2005 proposed a two-stage left-turn control method of roundabout based on the minimum average delay. The method is suitable to calculate the optimal cycle time under the unsaturated traffic flow. Cakici and Murat (2016) proposed an iterated signal timing method in which the optimal cycle length can be calculated by iterative progress. Both of them are full signalization methods of a roundabout.

Figure 6 Four phases in the two-stage left-turn control: (A) Phase 1, (B) Phase 2, (C) Phase 3, (D) Phase 4.

(Continued)

(Continued)

Two-stage left-turn control is typical full signalization of circulatory lane at roundabouts. In addition to the stop line on the approach, the second stop line on the circulatory lane is set up to control the left-turn traffic flow. Traffic signals instruments are installed before each stop line to eliminate the weaving flow conflicts on the circulatory lane. Left-turn vehicles on the circulatory lane will stop before red signals to avoid weaving.

The two-stage left-turn control method has four phases. In phase I, vehicles on the south and north entrances enter the roundabout. Turn-left vehicles stop in front of the second stop line. In phase II, the waiting vehicles before the second stop-line, from the north and south entrances, run out of the circulatory lanes. In phase III, vehicles on the east and west entrances enter the roundabout. Left-turn vehicles stop in the front of the corresponding second stop line. In phase IV, the waiting vehicles before the second stop-line, from the east and west entrances run out of the circulatory lanes. The phases diagram is shown in [Fig. 6](#).

In the method proposed by [Cakici and Murat \(2016\)](#), a formula (Equation 1) is developed for the design of signal timings regarding the storage area of the central island and circulating traffic flows. Signal timing of central island is calculated by this

Figure 6 (Continued)

formula. Different phase options are investigated in the research regarding some left-turn traffic flow scenarios and encouraging results are obtained by the proposed method. Detailed information about the method can be found in [Murat et al. \(2019\)](#).

$$\phi = \alpha + [(n - 1) \times \lambda] + \varepsilon \quad (1)$$

Where;

(ϕ): green time of central island (sec),

α : the lost times of departing vehicles in the storage area (sec),

n : the number of lines in storage area,

λ : departing headways of vehicles (sec),

ε : calibration coefficient for signal timing

For the past two decades, although the numbers of signalized roundabouts have been increased worldwide, traffic researchers still have many questions and uncertainties related to the operation and design of signalized roundabouts. Further research is needed to address improving capacity and LOS by considering environmental, economic and social effects. On the other hand, the variation of pedestrians and vehicle traffic flows may be considered in future works. Investigation of different signal timings and phase plans may also be interesting for future studies.

Biographies

Dr. Yetis Sazi MURAT graduated from Civil Engineering Dept. of Dokuz Eylül Univ., İzmir, Turkey in 1992. He has received MSc Degree from Pamukkale University in 1996 and PhD Degree from Istanbul Technical University in 2001. He worked as a visiting scholar at Virginia Tech University, Falls Church, United States in 2006 (6 months) and University of Nevada, Reno, United States in 2017 (6 months). He has published 85 research papers, 7 book chapters, and conducted many projects on different subjects of Transportation Engineering (especially about Traffic Engineering). He is currently working at Pamukkale University, Denizli, Turkey as a full-time Professor of Civil Engineering Department.

Guo Ruijun got a Bachelor's and Master's degree from the Wuhan University of Technology in 1999 and 2003; the PhD in transportation planning and management from Beijing Jiaotong University in 2013. He worked as a Post-Doctoral Scholar at Research Institute of Highway Science, China Ministry of Transportation from 2013–16. He worked as a visiting scholar at the University of Nevada, Reno, United States from 2017–18. He has published 40 research papers, two books, and two invention patents. Now he is an Associate Professor, Department of Transportation Engineering, Dalian Jiaotong University.

Introduction

In turbo roundabouts traffic entry, exit, and circulatory lanes are physically delimited by kerbs (see Fig. 1A). This implies a lower number of potentially conflicting points (Fig. 1B) between vehicle trajectories than conventional roundabouts (Fortuijn, 2009). By way of an example, in a turbo roundabout with four arms and two circulatory lanes, the number of conflicting points is equal to ten, while in a conventional roundabout with similar geometric characteristics there are 22 conflicting points (see Table 1). In many European countries, turbo roundabouts are utilized more and more. The geometric guidelines have been published in the Netherlands, Slovenia, Germany, Serbia, Slovakia, and Croatia.

Several turbo-roundabout layouts may be used: egg, basic turbo, knee, spiral and rotor, stretched-knee, and star. Undoubtedly, the most used is the *basic* turbo roundabout (Fig. 1A). The typical layout of the central island and circulatory lanes is generally designed through arcs of circumferences with different centers and radii, as shown in Fig. 2 for mini, standard, medium, and large *basic* turbo roundabouts (CROW, 2008). A lot of design guidelines lay down that the axis connecting the centers C_1 and C_2 in Fig. 2 must be inclined by around 30 degree to the axis of the minor road. In addition, ellipse arcs (Fig. 1C) or the Archimedean spiral can be used with the purpose for limiting the variation of the centrifugal acceleration around the circulatory lanes.

The radii values (Fig. 2) and the lane widths must be selected in such a way that the traffic speed along the turbo roundabout does not exceed 40 km/h.

Experimental measures on the Slovenian turbo roundabout of Fig. 1C ($R_{\max} \approx 25$ m) show that instantaneous vehicle speeds at entry are rather moderate (lower than 25 km/h, 15 m well ahead of the yield line) and accelerations are always lower than 2 m/s^2 at both entry and circulatory lanes (where they are generally below 1.5 m/s^2). Only at exit lanes accelerations prove to be slightly higher than 2 m/s^2 . As a rule, the following accidents may occur at double-lane roundabouts: failure to yield collisions, crashes for vehicle control loss, rear-end at entry, carriageway run-off, circulating-exiting collisions, and side-by-side collisions. The main difference between turbo roundabouts and conventional layouts lies in the lack of circulating-exiting and side-by-side conflicts, which are avoided with lane dividers, both at entries and on the circulatory lane. Compared to double-lane roundabouts, turbo roundabouts can provide the following potential benefits:

- reductions in the number of total potential accidents to between 40% and 50%;
- reductions in the number of potential accidents with injuries to between 20% and 30%.

Therefore, turbo roundabouts are more appropriate than conventional double-lane roundabouts in the cases requiring a higher safety level, for instance, in urban contexts where the traffic level of pedestrians and two-wheeler riders is very significant (Mauro et al., 2015).

Performance Analysis of Turbo Roundabouts

Turbo roundabouts are appropriate for daily traffic volumes of the order of 20,000–32,500 veh/day entering an intersection. The turbo-roundabout capacity is well higher than mini and single-lane roundabouts; it can be compared to the two-lane roundabout capacity and is lower than the signalized roundabout capacity, as can be seen from Fig. 3 (Brilon et al., 2014).

In order to study intersection functionality, it generally needs to determine either the total roundabout capacity or the simple single entry capacity, average vehicle delays, entry queue lengths, levels of service (LoS), and where required, pollutant emissions from traffic.

Functionality analyses can be carried out by traffic microsimulation softwares (Aimsun, Vissim, etc.) or closed-form models.

The calculation procedure implying the adoption of closed-form capacity models is schematized in the flowchart of Fig. 4. The physical lane division requires that the functionality of every driving lane be studied, in other words, it involves a lane-by-lane

Figure 1 (A) Basic turbo-roundabout layout; (B) potential conflict points; (C) first turbo roundabout in Slovenia.

Figure 2 Example of turbo-roundabout design criterion and typical radii values.

analysis. More specifically, through the capacity models based on the gap-acceptance theory, the preliminary step is to identify formulations for calculating the single-lane capacity at each entry (in function of the corresponding circulating flow). The second step is:

- To assess the impact of heavy vehicles on traffic (generally dependent on heavy vehicle types, heavy vehicle percentages, and total flow);
- To properly choose drivers' behavioral parameters, with special regard to the critical gap and the follow-up time;
- To estimate how a pedestrian flow may impact on single entry capacities.

Figure 3 Choice of roundabout types according to of daily volume.

These aspects are set out in detail in the further sections.

Values of the Critical Gap and Follow-Up Time in Turbo Roundabouts

The critical gap t_c and the follow-up time (or follow up headway) t_f play a crucial role in analyzing the functionality of unsignalized at-grade intersections in both conventional and turbo roundabouts (see further sections). These parameters are involved in the capacity expressions based on the gap-acceptance theory (the Harders formula and its derivatives). The t_c and t_f values estimated in studies performed in Europe since 2009 are shown in Fig. 5 (Guerrieri et al., 2018; Guerrieri et al., 2019; Macioszek, 2017). A recent research on how users behave in a roundabout (Fig. 1C) was conducted in Slovenia by analyzing vehicle trajectories on major and minor entry lanes with the digital image processing technique and estimated the following characteristic headways:

- critical gap: $t_c = 4.03\text{--}5.48$ s (obtained from 832 sample data);
- follow up time: $t_f = 2.52\text{--}2.71$ s (obtained from 1452 sample data)

Such values agree well with those provided by previous studies and shown in Fig. 5. In addition, the average values of psychotechnical times associated to heavy vehicles are always higher than the corresponding values in light vehicles. The histograms in Fig. 6 show t_c and t_f entry values for the minor and major arms (see Fig. 1C), distinguished for light and heavy vehicles. Depending on the entry lane, it can be observed that t_c values of heavy vehicles are higher by 15% ÷ 47% than those of light vehicles, instead t_f values of heavy vehicles are higher by 18% ÷ 25% than those of light vehicles.

Capacity Calculation

The layout of turbo roundabouts and the separation of circulatory lanes and entry arms require that the capacity of each entry lane be estimated. As turbo roundabouts are more appropriate in urban contexts, the capacity estimation model here suggested takes into account the different traffic components allowed to circulate in urban contexts (i.e., light vehicles, heavy vehicles, and pedestrians). Pedestrian crossings, located at arms near roundabout entries, can significantly influence the entry capacity. The models based on the gap-acceptance theory assume that circulatory lanes are always undersaturated. Thus, there is an essential need for the flow Q_i crossing the i th lane to be always lower than its capacity C_i . In other words, the saturation degree must be: $x_i = Q_i/C_i < 1$. The capacity of the circulatory lane is 1400–1600 veh/hour in single-lane sections (i.e., opposite entries 2 and 4 in Fig. 1A) and below 2500 veh/hour in two-lane sections (i.e., opposite entries 1 and 3 in Fig. 1A). Turbo roundabout entry lane capacity can be estimated through the following formulas:

- *Right-turn lane*: Tanner equation (adjusted by Brilon-Wu)

$$C_{E,R} = 3600 \cdot \left(1 - \frac{t_{\min} \cdot q_k}{3600}\right) \cdot \frac{1}{t_f} \cdot e^{-\frac{q_k}{3600} \left(t_c - \frac{t_f}{2} - t_{\min}\right)} \quad (1)$$

Figure 4 Functionality analysis flowchart for basic turbo roundabouts.

where: $C_{E,R}$ = the right-turn lane capacity at entry E [veh/h]; q_K = circulating vehicles opposite entry E, just next to the right-turn lane R [veh/h]; t_c = critical gap [s]; t_f = follow-up time [s] (t_c and t_f values have been specified in the above section), and $t_{\min} = 2.1$ seconds denotes the least headway between vehicles moving along the circulatory lanes [s].

- Through and left-turn lanes: Harders Model

$$C_{E,TLT} = q_k \cdot \frac{e^{-q_k \frac{t_{c,x}}{3600}}}{1 - e^{-q_k \frac{t_{f,x}}{3600}}} \quad (2)$$

with $C_{E,TLT}$, capacity of through and left-turn lanes; q_k , conflicting flow rate; $t_{c,x}$ and $t_{f,x}$ critical gap and follow-up time, respectively; $q_k = Q_{c,e} + Q_{c,i}$; $Q_{c,e}$ = circulating flow on the outer circulatory lane; $Q_{c,i}$ = circulating flow on the inner circulatory lane. The critical gap ($t_{c,x}$) and the follow-up time ($t_{f,x}$) can be assumed as: $t_{c,x} = 6,4$ s; $t_{f,x} = 3,5$ s.

The passenger car equivalents (PCEs) can reasonably assume the following values: 1 heavy vehicle = $1.5 \div 2$ cars (depending on heavy vehicle types and traffic flow), 1 heavy truck = 2.5 cars; 1 articulated truck = 3 cars, 1 bicycle/motorbike = 0.5 cars.

- Effect of pedestrian flow on entry capacity

Figure 5 Critical headways and follow-up times at turbo roundabouts.

Figure 6 Average values of the critical gap (t_c) and follow up time (t_f) for light and heavy vehicles.

The German method can be used (Mauro, 2010). The model implies the determination of a capacity reduction factor M . For a single entry lane the reduction factor M is as follows:

$$M = \frac{1119.5 - 0.715 \cdot q_k - 0.644 \cdot Q_{ped} + 0.00073 \cdot q_k \cdot Q_{ped}}{1069 - 0.65 \cdot q_k} \quad (3)$$

where: q_k = conflicting flow rate (pcu/h); Q_{ped} = pedestrian flow (ped/h).

By particularizing to turbo roundabouts, it results:

$$M_{E,R} = \frac{1119.5 - 0.715 \cdot Q_{c,e} - 0.644 \cdot Q_{ped} + 0.00073 \cdot Q_{c,e} \cdot Q_{ped}}{1069 - 0.65 \cdot Q_{c,e}} \quad (4)$$

$$C_{E,R}^{ped} = C_{E,R} \cdot M_{E,R} \quad (5)$$

$$M_{E,TLT} = 1119.5 - 0.715 \cdot (Q_{c,e} + Q_{c,i}) - 0.644 \cdot Q_{ped} + 0.00073 \cdot \frac{(Q_{c,e} + Q_{c,i}) \cdot Q_{ped}}{1069 - 0.65 \cdot (Q_{c,e} + Q_{c,i})} \quad (6)$$

$$C_{E,TLT}^{ped} = C_{E,TLT} \cdot M_{E,TLT} \quad (7)$$

Figure 7 Comparison between models for entry lane capacities and capacity reduction factor values.

where: $M_{E,R}^{ped}$ = right-turn lane pedestrian capacity reduction factor; $M_{E,TLT}^{ped}$ = through and left-turn lane pedestrian capacity reduction factor; $C_{E,R}^{ped}$ = right-turn lane vehicle capacity considering impact on pedestrians [veh/h]; $C_{E,TLT}^{ped}$ = through and left-turn lane vehicle capacity considering impact on pedestrians [veh/h]; $C_{E,R}$ = right-turn lane vehicle capacity (no pedestrian crossings, only vehicles) [veh/h]; $C_{E,TLT}$ = through and left-turn lane vehicle capacity (no pedestrian crossings, only vehicles) [veh/h].

Fig. 7 shows the entry lane capacities and reduction factors in function of the circulating flow rate.

Each entry lane at a turbo roundabout is characterized not only by different capacity values (C_i), but also by different flow rates (Q_i); it results that the saturation degree ($x_i = Q_i/C_i$) can differ between lanes of the same entry and the total entry capacity is not a simple sum of the single lane capacities. For these reasons the effective entry capacity C_E^{ped} can be obtained from:

$$C_E^{ped} = \frac{(Q_{E,R} + Q_{E,TLT})}{\max \left[\frac{Q_{E,R}}{C_{E,R}^{ped}}, \frac{Q_{E,TLT}}{C_{E,TLT}^{ped}} \right]} \quad (8)$$

The previous equation shows that capacity of each entry depends on the capacity of the single lane and thus on: (1) conflicting flow; (2) circulating flows at the circulatory carriageway; (3) user behavior (through parameters t_c , t_f , t_{min}); (4) traffic demand balance at entry arms; and (5) pedestrian flow.

Delays and Level of Service Estimation

After calculating the capacity and saturation degree of each lane (in case of lane undersaturation and pedestrian flow), the average delay per vehicle can be estimated at the lane under examination, by means of the following equations (in [Tollazzi et al., 2016](#)):

$$D_{E,TLT}^{ped} = \frac{3600}{C_{E,TLT}^{ped}} + 900 \cdot T \cdot \left[\frac{Q_{E,TLT}}{C_{E,TLT}^{ped}} - 1 + \sqrt{\left(\frac{Q_{E,TLT}}{C_{E,TLT}^{ped}} - 1 \right)^2 + \left(\frac{3600}{C_{E,TLT}^{ped}} \right) \cdot \frac{\left(\frac{Q_{E,TLT}}{C_{E,TLT}^{ped}} \right)}{450 \cdot T}} \right] + 5 \cdot \min \left[\frac{Q_{E,TLT}}{C_{E,TLT}^{ped}}, 1 \right] \quad (9)$$

$$D_{E,R}^{ped} = \frac{3600}{C_{E,R}^{ped}} + 900 \cdot T \cdot \left[\frac{Q_{E,R}}{C_{E,R}^{ped}} - 1 + \sqrt{\left(\frac{Q_{E,R}}{C_{E,R}^{ped}} - 1 \right)^2 + \left(\frac{3600}{C_{E,R}^{ped}} \right) \cdot \frac{\left(\frac{Q_{E,R}}{C_{E,R}^{ped}} \right)}{450 \cdot T}} \right] + 5 \cdot \min \left[\frac{Q_{E,R}}{C_{E,R}^{ped}}, 1 \right] \quad (10)$$

where: $D_{E,R}^{ped}$ = average control delay for the right-turn lane (s/veh); $D_{E,TLT}^{ped}$ = average control delay for through and left-turn lanes (s/veh); T = reference time (h), ($T = 1$ for a 1-h analysis, $T = 0.25$ for a 15-min analysis). Generally speaking, delays will differ at the two entry lanes; so the level of service of the right-turn lane is to be differentiated from the corresponding level of service at the through and left-turn lanes. The total average delay at entries is expressed by the following relation:

$$D_E^{ped} = \frac{D_{E,R}^{ped} \cdot Q_{E,R} + D_{E,TLT}^{ped} \cdot Q_{E,TLT}}{Q_{E,R} + Q_{E,TLT}} \quad (11)$$

where $D_{E,R}^{ped}$, $Q_{E,R}$, $D_{E,TLT}^{ped}$, $Q_{E,TLT}$ are respectively delays and flow rates at the two lanes of entry E. In order to define the level of service at each entry lane, valuable indications can be given by [HCM \(2010\)](#), as shown in [Table 2](#).

Table 2 Level of service

Delay (s/veh)	Level of service by volume-to-capacity ratio

**Figure 8** (A) Flower roundabout; (B) target roundabout; (C) four flyover roundabout

Comparison With Other Types of One and Two-Level Roundabout Intersections

A turbo roundabout may be preferable in specific traffic conditions, which can be also identified by comparing the following roundabout types:

- Basic turbo roundabout (Fig. 1A)
- Flower roundabout with right-turn bypass lane with yield sign (Flower-yield) or with free-flow right-turn (Flower-free) (Fig. 8A)
- Target roundabout (Fig. 8B)
- Four flyover roundabout (Fig. 8C)
- Standard roundabout with an entry lane and a circulatory lane (1 + 1)
- Standard roundabout with an entry lane and two circulatory lanes (1 + 2)
- Standard roundabout with two entry lanes and two circulatory lanes (2 + 2).

The capacity models presented in the previous sections were used for traffic simulations of turbo roundabouts. On the other hand, the models described in the HCM 2010 manual were used for standard roundabouts; the capacity models used for Flower, Target, and Four flyover roundabouts are explained in Tollazzi et al. (2016).

Three test matrices ρ_1 , ρ_2 , and ρ_3 , for traffic demand, were taken into account. The total entry ranging between 225 veh/h and 4,775 veh/h (equally distributed among the four arms of each intersection) flowed into the road intersections. The origin destination (OD) matrices were:

- OD Matrix ρ_1 = 72% of vehicles turn right, 13% cross, and 15% turn left;
- OD Matrix ρ_2 = 13% of vehicles turn right, 72% cross, and 15% turn left;
- OD Matrix ρ_3 = 15% of vehicles turn right, 13% cross, and 72 % turn left.

$\rho_1 =$	0	0.72	0.12	0.15	$\rho_2 =$	0	0.13	0.72	0.15	$\rho_3 =$	0	0.15	0.13	0.72
	0.15	0	0.72	0.13		0.15	0	0.13	0.72		0.72	0	0.15	0.13
	0.13	0.15	0	0.72		0.72	0.15	0	0.13		0.13	0.72	0	0.15
	0.72	0.13	0.15	0		0.13	0.72	0.15	0		0.15	0.13	0.72	0

Figure 9 Average delays at roundabouts for OD Matrix p1.

Figure 10 Average delays at roundabouts for OD Matrix p2.

Figure 11 Average delays at roundabouts for OD Matrix p3.

Figs 9, 10, and 11 show the average delays in function of the total entering traffic. As clearly seen, the target roundabout (two-level roundabout, Fig. 8B) produces lower delays in all traffic conditions examined. Among the at-grade intersections, standard roundabouts (2 + 2) provide lower delays than other standard types [(1 + 1) and (1 + 2)]. On the other hand, turbo roundabouts guarantee lower average delays, and thus they would be preferable to at-grade intersections if the entering flow turns mainly right (i. e., OD Matrix p1, see Fig. 9).

Introduction

The vehicular flow along a given road section is akin to the water flowing through a pipe. The volume of water that can flow through a section of pipe for a given period depends on the geometry of the pipe and the speed of the water. By the same token, along a given road section, the volume of vehicles that can travel is confined by certain factors like road width and speed of the traffic. In general, the capacity of a road at a particular time can be described as the number of vehicles that can travel along the section of the road. This is a key element in governing the planning, analysis, and operation of a road facility. A clear understanding of the capacity helps in a safe, smooth, and economic operation of traffic through the facility. **Figure 1** illustrates the dichotomy of basic traffic stream parameters. The quantitative measure of the traffic stream explains the capacity while the Level-of-Service (LOS)—the level of quality one can derive from the traffic facility—is reflected by the qualitative measures of the traffic stream.

During the initial era of traffic flow research, the concept of capacity was associated with the issue of congestion, and the researchers defined capacity in terms of the maximum traffic volume and density. Even though there exists a complex relationship between demand, volume, and capacity, they are a different measure of traffic. **Figure 2** differentiates the concept of volume, demand, and capacity.

Like other basic concepts, the sense of capacity has evolved. In 1950, Highway Capacity Manual (HCM) formally defined the concept of highway capacity for the first time. It did so by defining three unique capacity values: basic capacity, possible capacity, and practical capacity. They are characterized by the roadway and traffic conditions under which the capacity is estimated. The basic capacity considers the most nearly ideal conditions that can be attained. The prevailing conditions are considered in the possible capacity and the practical capacity also accounts for the prevailing conditions without the traffic density being so high as to cause unreasonable delay, hazard, or restrictions to maneuverability. The 1965 HCM replaced these three capacity values with a single one and revised in the subsequent editions of HCM. According to HCM, the capacity of a system element is the maximum sustainable hourly flow rate at which persons or vehicles reasonably can be expected to traverse a point or uniform section of a lane or roadway during a given time period under prevailing roadway and traffic conditions.

Concepts of Intersection Capacity

An intersection is an element of a road network, where two or more vehicular movements share a common space. This space enables the vehicles to turn to their desired direction and continue to the destination. But the uncontrolled movement of traffic in this area

Figure 1 Traffic stream parameters.

Figure 2 Volume, demand, and capacity.

results in the conflict of vehicles. It is vital to segregate the vehicles so that the potential conflict points are removed. This can be achieved either spatially or temporally, where vehicles find their safe time slot or vehicles are allocated a time slot to make their maneuver. Based on the traffic controlling measures, intersections are categorized into at-grade intersections and grade-separated intersections (Figure 3). Every traffic facility has a specific measure of effectiveness to quantify the quality one can derive from the traffic facility. For grade-separated intersections, the measure of effectiveness used is density and for at-grade intersection, it is control delay.

Just as the road section, intersections also have the capacity. As mentioned earlier, intersection capacity is also influenced by different factors like geometric conditions, traffic flow, vehicular composition, and signal timing. It is more appropriate to discuss the capacity of the intersection as the capacity of individual approaches. The analysis of grade-separated intersection is similar to that of road links. In this chapter, we will focus on the capacity analysis of the at-grade intersections, under the headings of a signalized intersection, unsignalized intersection, and roundabouts.

The Capacity of Signalized Intersection

Signal operations in a road section interrupt the vehicular flow and which causes delays. Saturation flow will reflect this effect of the signalized intersection. The concept of saturation is used for estimating the capacity of the signalized intersection. Saturation flow can be defined as the rate at which the vehicles that have been waiting in a queue during the red interval cross the stop line during the green interval. The steps for estimating signalized intersection capacity can be simplified as follows:

1. Collect the information regarding the geometric and traffic characteristic of intersection along with the control characteristics. Geometric characteristics include the lane width, number of lanes, gradient, parking condition, etc. Traffic characteristics include demand by movement, base saturation flow, peak hour factor, approach speed, pedestrian activity, percentage of heavy vehicles, etc. Cycle length, green time phase plan, etc., comes under the control characteristics.
2. Calculate the saturation flow s_i for each lane group in the intersection.
3. Compute the capacity based on the saturation flow and effective green ratio for the lane group. If the effective green time on an approach i is g_i and the cycle time is C then the capacity on the given approach is given by equation (1).

Figure 3 Types of intersection.

$$\text{Capacity of lane group } i = s_i \frac{g_i}{C} \quad (1)$$

Where,

S_i = Saturation flow of the lane group i .

g_i = Effective green time on an approach i .

C = Cycle time

Saturation flow can be either measured directly from the field or estimated theoretically. The later method, estimates the saturation flow by adjusting the base saturation value (under ideal condition) according to the roadway and traffic condition. Estimation of saturation flow is highly location specific and also affected by the driving behavior of people. This spurred several nations to develop their guidelines for measuring and estimating the saturation flow.

United States of America

According to the HCM (2016), saturation flow rate for each lane-group is given by equation (2). By considering a saturation headway of 1.9 seconds, a base saturation flow rate of 1900 passenger cars per hour per lane is usually adopted.

$$s = s_0 \times f_w f_{HV} f_g f_p f_{bb} f_a f_{LU} f_{LT} f_{RT} f_{Lpb} f_{Rpb} \quad (2)$$

Where,

s = adjusted saturation flow rate for the subject lane group in PCU per hour per lane.

s_0 = base saturation flow rate per lane in PCU per hour per lane.

f_w = lane width adjustment factor.

f_{HV} = adjustment factor for heavy vehicles in the traffic stream.

f_g = approach grade adjustment factor.

f_p = adjustment factor for the existence of a parking lane and parking activity adjacent to lane group.

f_{bb} = adjustment factor for the blocking effect of local buses that stop within the intersection area.

f_a = adjustment factor for area type.

f_{LU} = lane utilization adjustment factor.

f_{LT} = adjustment factor for left turns in lane group.

f_{RT} = adjustment factor for right turns in lane group.

f_{Lpb} = pedestrian adjustment factor for left-turn movements.

f_{Rpb} = pedestrian-bicycle adjustment factor for right-turn movements.

India

The base saturation flow in Indian intersection is estimated based on the width of the approach, Indo-HCM (2017) discusses the relationship between the base saturation flow and the width of the approach. Equation (3) gives the base saturation flow rate per unit width of the road. The prevailing saturation flow of the intersection approach for the lane group under consideration is then obtained from equation (4).

Table 1 Base saturation flow by environment class and lane type

<i>Environment class</i>	<i>1</i>	<i>Lane type</i> <i>2</i>	<i>3</i>

Source: Austroads, 2020

$$USF_0 = \begin{cases} 630; & \text{for } w < 7.0 \text{ m} \\ 1140 - 60w; & \text{for } 7.0 \leq w \leq 10.5 \text{ m} \\ 500; & \text{for } w > 10.5 \text{ m} \end{cases} \quad (3)$$

Where,

 USF_0 = unit base saturation flow rate in PCU per hour per meter. w = effective width of approach in meters.

$$S = w \times USF_0 \times f_{bb} f_{br} f_{is} \quad (4)$$

Where,

 S = adjusted saturation flow rate in PCU per hour. w = effective width of the approach in meter used by the lane group. USF_0 = unit base saturation flow rate. f_{bb} = adjustment factor for bus blockage due to the curbside bus stop. f_{br} = adjustment factor for the blockage of through vehicles by standing right-turning vehicles waiting for their turn. f_{is} = adjustment factor for the initial surge of vehicles due to approach flare and anticipation effect.**Indonesia**

The base saturation flow for different approach types is obtained from the graphs reported in the [Indonesian HCM \(1993\)](#). Then the prevailing saturation flow value is calculated using the equation (5).

$$S = S_o \times f_{CS} \times f_{SF} \times f_G \times f_p \times f_{RT} \times f_{LT} \quad (5)$$

Where,

 S = prevailing saturation flow in vehicles per hour. S_o = base saturation flow. f_{CS} = adjustment factor for city size. f_{SF} = adjustment factor for side friction. f_G = adjustment factor for the gradient. f_p = adjustment factor for parking. f_{RT} = adjustment factor for right turns in the lane group. f_{LT} = adjustment factor for left turns in the lane group.**Australia**

Australian Road Research Board defined base saturation flow by environment class and lane type as shown in [Table 1 \(Austroads, 2020\)](#). This base saturation flow is adjusted to match the prevailing condition to estimate the saturation flow. This method is summarized in equation (6).

Table 2 Summary of the base saturation flow estimation and adjustment factors for prevailing saturation flow

Sl. No	Country	Base saturation flow	No. of adjustment factors

$$S = \frac{f_w f_g}{f_c} S_0 \quad (6)$$

Where,

S = adjusted saturation flow in vehicles per hour.

S_0 = base saturation flow from **Table 1**.

f_w = lane width adjustment factor.

f_g = gradient adjustment factor.

f_c = Traffic compensation factor.

United Kingdom

The prevailing saturation flow at signalized intersections in the United Kingdom is obtained using the model developed based on the lane geometry and composition of traffic flow. This predictive model is evolved out of the study done at multiple signalized intersection at various sites throughout the United Kingdom. According to (Kimber et al., 1986) saturation flow at signalized intersections in the United Kingdom have a significant influence on the condition of the road surface (wet/dry), the proportion of turning traffic, radius of turn, gradient, lane position (nearside, non-nearside), lane width and the number of lanes at the stop line.

Summary

The intersection capacity of a signalized intersection depends upon the prevailing saturation flow rate and the effective green time ratio. The factors affecting the prevailing saturation flow differs from place to place, it is difficult to have a common methodology for estimating capacity. **Table 2** summarizes the base saturation flow estimation procedure practiced by some nations .

The Capacity of Unsignalized Intersection

The unsignalized intersection can be broadly categorized into priority intersection and uncontrolled intersection. In priority intersections, the intersecting roads are given a definite priority over the other, while in the uncontrolled intersection, all the intersecting roads have equal importance. The traffic flow through the unsignalized intersection is governed by signs namely, stop or yield sign. Based on these traffic control measures; the intersection can be a two-way stop-controlled intersection (TWSC) or all-way stop-controlled intersection (AWSC). In the TWSC intersection, the stop sign is provided on the minor street.

The movement of vehicles through the intersection follows the gap acceptance theory. Any traffic stream at an unsignalized intersection moves by accepting gaps in the conflicting streams. The gap availability is inversely related to the number and volume of conflicting streams and the size of the critical gap. In an unsignalized intersection, there exists a hierarchy of movement, **Figure 4** illustrates this priority of movements at a typical four-leg and a typical T-intersection. Vehicles traversing at an unsignalized intersection accepts the gaps in this prioritized manner.

Often, at unsignalized intersections, an approach may be shared by more than one movement. In such cases, the vehicles of a particular movement might be caught behind the vehicles of other movement groups, and its gap of interest never gets fully utilized. That is, even if a gap is available it may not be used because the vehicle, which could have used it had other vehicles ahead of it in the queue. These factors influence the capacity and are sometimes incorporated in capacity calculations.

The traffic behavior at an unsignalized intersection is different across the world in terms of give-way rules, lane discipline, queuing rules, and the enforcement of traffic regulation. It is very difficult to describe such practices with behavioral models like gap-acceptance models. This makes the adoption of a single methodology for capacity estimation infeasible. The analysis of unsignalized intersection can be broadly categorized into two regression (empirical) models and analytical models. The regression models establish a statistical relationship between geometric characteristics and the capacity based on the field data. The analytical models are developed based on the traffic flow theory and actual driver behavior.

Figure 4 Priority of movements. Source: HCM, (2016)

Figure 5 Steps for estimating the unsignalized intersection capacity Source: HCM (2016).

United States of America

Figure 5 illustrates the methodology used for estimating unsignalized intersection capacity in the United States the capacity is estimated based on the conflicting volume, critical gap, and follow-up headway calculated. The effect of the gradient, heavy vehicle, two-stage gap acceptance process, and type of geometry is considered in the calculation of critical gap and follow-up time. The computation of critical gap and follow-up headway is as shown in equation (7) and (8), respectively (HCM, 2016).

$$t_{c,x} = t_{c,base} + t_{c,HV}P_{HV} + t_{c,G}G - t_{3,LT} \quad (7)$$

where

$t_{c,x}$ = critical gap/headway for movement x.

$t_{c,base}$ = base critical headway.

Figure 6 Methodology for estimating the capacity of an unsignalized intersection in India. Source: *Indo-HCM (2017)*

$t_{c,HV}$ = heavy vehicles adjustment factor.

P_{HV} = proportion of heavy vehicles for movement.

$t_{c,G}$ = adjustment factor for the grade.

G = percent grade.

$t_{3,LT}$ = adjustment factor for intersection geometry

$$t_{f,x} = t_{f,bass} + t_{f,HV}P_{HV} \quad (8)$$

where

$t_{c,x}$ = follow-up headway for movement x.

$t_{c,bass}$ = base follow-up headway.

$t_{c,HV}$ = adjustment factor for heavy vehicles.

P_{HV} = proportion of heavy vehicles for movement.

Using the conflicting volume, critical gap, and follow-up time for a given movement, its potential capacity is then estimated using gap acceptance models. According to *HCM (2016)*, the potential capacity of a movement is computed by equation (9). This potential capacity is then adjusted to reflect the impedance from higher-priority movements, sharing of lanes, and other factors.

$$C_{p,x} = v_{c,x} \frac{e^{-v_{c,x}t_{c,x}/3600}}{1 - e^{-v_{c,x}t_{f,x}/3600}} \quad (9)$$

Where,

$C_{p,x}$ = potential capacity of movement x in vehicles per hour.

$v_{c,x}$ = conflicting flow rate for movement x in vehicles per hour.

$t_{c,x}$ = critical headway for minor movement x.

$t_{f,x}$ = follow-up headway for minor movement x.

The movement capacity is then calculated by adjusting the potential capacity. The adjustment factor is obtained by multiplying the probability that each impeding movement will be blocking the subject vehicle. Movement capacity is found by equation (10) (*HCM, 2016*).

$$C_{m,x} = C_{px} \prod_{i,j} P_{vi} P_{pj} \quad (10)$$

Where,

$C_{m,x}$ = Movement capacity, movement x. in vehicles per hour.

C_{px} = potential capacity, movement x in vehicles per hour.

P_{vi} = probability that impeding vehicular movement i is not blocking the subject flow.

P_{pj} = probability that impeding pedestrian movement j is not blocking the subject flow.

India

In India, due to weak enforcement of traffic regulations and lack of understanding of priority rules among road users, no distinction is made in the Indo-HCM between a TWSC and AWSC intersection (*Indo-HCM, 2017*). The manual clearly defines the conditions for a base intersection. If the candidate intersection does not conform to these conditions (non-base intersection), adjustment

Table 3 The capacity of unsignalized intersection summary

Sl. No	Country	Flow rate	Capacity estimation methodology	Critical gap estimation	Follow-up time
1	United States	veh/h	Gap acceptance method	Adjusting the base value	Adjusting the base value
2	Indonesia	pcu/h	Empirical method	N.A.	N.A.
4	India	pcu/h	Gap acceptance method	Occupancy time method	60% of the critical gap

Source: HCM (2016); Indo-HCM (2017); Indonesian Highway Capacity Manual (1993)

factors need to be applied for the deviations from the base conditions. The follow-up time is assumed as 60% of the critical gap. Figure 6 illustrates the steps involved in the estimation of unsignalized intersection capacity in India.

Occupancy Time Method (OTM) is used for the calculation of critical gaps. OTM considers the actual driver behavior on unsignalized intersections. It captures the actual clearing pattern of the conflict area and traffic interactions. The critical gap for different movements is then adjusted for the proportion of heavy vehicles in the conflicting traffic streams. According to the Indo-HCM (2017), the prevailing critical gap for any movement can be obtained using the equation (11).

$$t_{c,x} = t_{c,bass} + f_{LV} \times \ln(P_{LV}) \quad (11)$$

Where,

$t_{c,x}$ = critical gap for vehicle type x.

$t_{c,bass}$ = base critical gap value for corresponding vehicle type executing the same movement.

f_{LV} = adjustment factor for large vehicles.

P_{LV} = proportion of large vehicles in the conflicting traffic stream.

Once the value of the critical gap, follow-up time, and conflicting flow rates is estimated, then the capacity of the movement is calculated from equation (12) (Indo-HCM, 2017).

$$C_x = a \times v_{c,x} \frac{e^{-v_{c,x}(t_{c,x}-b)/3600}}{1 - e^{-v_{c,x}t_{f,x}/3600}} \quad (12)$$

Where,

C_x = capacity of movement 'x' in PCU per hour

$v_{c,x}$ = conflicting flow rate corresponding to movement x in PCU per hour

$t_{c,x}$ = critical gap of standard passenger cars for movement 'x'

$t_{f,x}$ = follow-up time for movement 'x'

'a' and 'b' = adjustment factors based on intersection geometry

Indonesia

Indonesia follows the regression model approach, the prevailing capacity of unsignalized intersections in Indonesia is estimated by applying the corrections to the base capacity. The base capacity for different types of intersections is tabulated in the Indonesian Highway Capacity Manual (1993). The total capacity for all arms of the intersection is calculated from equation (13).

$$C = C_o \times F_w \times F_M \times F_{CS} \times F_{RF} \times F_{LT} \times F_{RT} \times F_N \quad (13)$$

Where,

C_o = Capacity for an intersection type for a predetermined ("base") set of influencing conditions.

F_w = Correction factor for base capacity due to intersection entry width.

F_M = Correction factor for base capacity due to major road median type.

F_{CS} = Correction factor for base capacity due to city size.

F_{RF} = Correction factor for base capacity due to road environment type and side friction level.

F_{LT} = Correction factor for base capacity due to left turning.

F_{RT} = Correction factor for base capacity due to right turning.

F_N = Correction factor for base capacity due to road flow split.

Summary

The capacity of a movement depends on (1) the number of conflicting movements and conflicting volumes, (2) critical gap size, and (3) hierarchical position of the movement among all movements vying for a gap at the intersection. Different techniques are practiced across the globe to estimate the critical gap and capacity of different movements at an unsignalized intersection. The most popular technique is the gap acceptance approach, that assumes a minor street vehicle to come to a halt on its arrival at the intersection and wait for a suitable gap in the conflicting traffic stream to complete its desired maneuver. Table 3 summarizes the capacity estimation method practiced in the United States, India, and Indonesia.

Figure 7 Roundabout approach. Source: HCM (2016)

Table 4 Capacity equation for roundabouts in the United States

Entering lanes	Conflicting circulating lanes	Capacity equation
1	1	$C_{e,pce} = 1130 \text{Exp}[-1.0 \times 10^{-3} v_{c,pce}]$
2	1	$C_{e,pce} = 1130 \text{Exp}[-1.0 \times 10^{-3} v_{c,pce}]$
1	2	$C_{e,pce} = 1130 \text{Exp}[-0.7 \times 10^{-3} v_{c,pce}]$

Capacity of Roundabouts

A roundabout is a class of at-grade intersection where the vehicles approaching the intersection are forced to move around a central island in one direction and move out of the roundabout into their desired direction. The capacity of the roundabout depends upon the circulating flow (V_c) that conflicts with the entry flow (V_e) and the geometric elements of the roundabout (see Figure 7).

The rate at which vehicles can enter the roundabout is influenced by the circulating flow. The size of the gap and the circulating flow is inversely proportional, thus a low-circulating flow results in a higher gap, which helps the vehicles to enter the roundabout without much delay. As the circulating flow increases, the rate at which vehicles entering the roundabout decreases. The entry flow is also affected by the geometric features of the roundabout, such as the entry width, width of the circulatory roadways, and the number of lanes at the entry on the roundabout.

United States of America

According to HCM (2016), the roundabout analysis in the United States is a combination of simple, lane-based regression, and gap-acceptance. The capacity equation for single-lane and multi-lane roundabouts is mentioned in Table 4 the capacity values are adjusted for the presence of heavy vehicles.

Where,

$C_{e,pce}$ = Lane capacity, adjusted for heavy vehicles.

$C_{e,R,pce}$ = Capacity of the right entry lane, adjusted for heavy vehicles.

$C_{e,L,pce}$ = Capacity of the left entry lane, adjusted for heavy vehicles.

$v_{c,pce}$ = Conflicting flow rate.

India

According to Indo-HCM (2017), more than 70% roundabouts in India possess 20–70 m diameter and the average diameter of roundabouts in Indian cities/town is 35 m. Thus, the method mentioned in Indo-HCM confines to roundabouts having this diameter range. Indo-HCM adopted the exponential model from HCM, as mentioned in equation (14–16). The values of the critical gap and follow-up time parameters for roundabouts of different diameters are presented in Indo-HCM. The follow-up time is considered as 0.75 times the critical gap. Using these values, the capacity equations for a varying range of diameters is tabulated in Table 5.

$$\text{Capacity, } C = A \times \text{Exp}(-B \times Q_c) \quad (14)$$

Table 5 Roundabout capacity equations in India

$$A = 3600/T_f \quad (15)$$

$$B = (T_c - 0.5 \times T_f)/3600 \quad (16)$$

Where,

 T_f = Follow-up time in seconds T_c = Critical gap in seconds Q_c = Circulating flow in PCU per hour**Indonesia**

According to the [Indonesian Highway Capacity Manual \(1993\)](#), the capacity under the prevailing condition is obtained by adjusting the base capacity. Base capacity is calculated using the equation (17). Where the input variables are weaving width W , weaving width/entry width ratio WE/W , weaving percentage $W\%$, and weaving width/length-ratio W/L . The actual capacity is then computed by equation (18).

$$C_0 = 135 \times W^{1.3} \times (1 + WE/W)^{1.5} \times (1 - W\%/300)^{0.5} / (1 + W/L)^{1.8} \quad (17)$$

$$C = C_0 \times F_{CS} \times F_{RF} \quad (18)$$

Where,

 C_0 = Base capacity F_{CS} = City size correction factor F_{RF} = Road environment type and side friction correction factor**Summary**

The capacity of a roundabout is influenced by the flow pattern and the geometry of the roundabout. As in the unsignalized intersection, the capacity analysis of roundabouts also based on the gap acceptance theory. In [HCM \(2016\)](#), the capacity equation

**Figure 8** Application of capacity estimation.

is selected based on the number of the lane and in [Indo-HCM \(2017\)](#), the capacity equation is defined by the diameter of the roundabout.

Conclusion

Modeling the capacity of a traffic facility will give an upper hand in the planning, analysis, and operation of the facility. The estimation capacity is influenced by the prevailing roadway, traffic, and control conditions. Thus, the actual capacity observed may vary day to day depending upon several factors like the weather condition, ambient light, and familiarity of drivers, but still, it is important to have a good estimate of capacity values. Most of the capacity analysis models include the determination of capacity under the ideal roadway, traffic, and control conditions, later, it is adjustments for prevailing conditions. According to the intended purpose of future analysis, the precision of capacity estimation varies as shown in [Figure 8](#).

FFTT free-flow travel time of the target section

ATT actual travel time

$\mu_{\max}$ capacity of the bottleneck

$\lambda(t)$ arrival rate of traffic demand

$A(t)$ cumulative count of arrival from upstream

$A'(t)$ cumulative count of arrival to the bottleneck

$D(t)$ cumulative count of departure from the bottleneck

When vehicles travel on roadway, they experience delay by several reasons. The most typical delay is caused by traffic jam, which occurs when many vehicles try to use a certain roadway section in a short-time period. Delay also occurs at signalized intersections, where vehicles have to stop and wait during red signal. Moreover, delay can be seen not only on roadway but also in any kinds of queueing system, such as, cashier, ticket booth, passport control, and so on. Delay is normally considered as negative output from a queueing system, therefore it is often used to evaluate the performance of the system.

Definition

Delay is defined as increment of actual travel time from free-flow travel time. Here, free-flow travel time is time duration that a vehicle can travel along a certain section of roadway at its desired speed without any influence of other vehicles, control devices such as traffic signals. On the other hand, actual travel time is time duration that a vehicle actually spends for the same roadway section. (May, 1990; Transportation Research Board, 2016)

When we consider delay at a signalized intersection, vehicle's travel time without any acceleration, deceleration or stop in passing the intersection is used as free-flow travel time. Therefore, even though there are no other vehicles and no queue at the stop line of the intersection, a vehicle may experience signal control delay if it stops by red signal.

In some cases in practice, vehicle-stopping time by red signal is used as signal control delay. It becomes smaller than the original definition as it does not include deceleration status of vehicles by signal or congestion. However, they are usually very closely correlated and this method is practical because it is easy to identify the status of vehicles, that is, moving or stopping.

Theoretical Explanation by Cumulative Curve

Suppose a simple roadway section that has a bottleneck whose capacity is $\mu_{\max}$ in the downstream as shown in Figure 1. And, observation point A is set in the upstream enough where queue tail does not reach and another observation point B is set immediately downstream of the bottleneck. Now traffic demand $\lambda(t)$ arrives from the upstream and flows into the bottleneck. While $\lambda(t)$ is less than $\mu_{\max}$, vehicles can travel this section by free flow travel time (FFTT), which is assumed almost constant value. When $\lambda(t)$ exceeds the capacity $\mu_{\max}$, queue is formed at the bottleneck and vehicles have to spend more travel time (actual travel time: ATT) than FFTT. Here, delay is formulated as ATT-FFTT according to the definition.

Figure 1 Simple roadway section.

Figure 2 Plot of vehicle passing time.

Figure 3 Arrival curve and departure curve.

Now, let's consider vehicle's passing time at the upstream point A and the downstream point B. The recorded data is plotted as shown in **Figure 2**. Here, the horizontal axis is time and the vertical axis is the cumulative number of passing vehicles. When the first vehicle passes, two points are plotted at time t_{1A} and t_{1B} on the bottom line. Next, the second vehicle passes at time t_{2A} and t_{2B} on the line above the previous one.

By repeating this process and connecting the plots, the cumulative number of passing vehicles at the point A and B and their passing time can be obtained as cumulative curves as shown in **Figure 3**. The upstream curve is called as "Arrival Curve," denoted as $A(t)$, whereas the downstream curve is called as "Departure Curve," denoted as $D(t)$. The arrival rate $\lambda(t)$ is shown as the slope of the arrival curve $A(t)$, whereas the capacity of the bottleneck $\mu_{\max}$ is shown as the maximum gradient of the departure curve $D(t)$.

As the i th vehicle is shown as a certain height in this figure, its actual travel time (ATT) can be obtained by the horizontal difference of the two curve $A(t)$ and $D(t)$. Here, ATT is composed of FFIT and delay. As FFIT is common for all the vehicles, let's shift $A(t)$ to the right by this amount. Then, new curves $A'(t)$ and $D(t)$ are obtained as shown in **Figure 4**. Here, the horizontal difference of $A'(t)$ and $D(t)$ is the delay of the i th vehicle. And when there is no delay, these curves become the same line, that is $A'(t) = D(t)$. Then, we can understand that the delay occurs only the period that $A'(t)$ and $D(t)$ are apart. As vehicles that experience delay pass during this time period, the area surrounded by $A'(t)$ and $D(t)$ can be regarded as the total delay experienced by the passing vehicles by this queue. Therefore, we can evaluate the amount of the total delay by calculating the area from this graph. The unit of the total delay is (vehicle-hours), because it is multiplication of time and number of vehicles. (Daganzo, 1997)

Assumption to Use Cumulative Curve

As explained, cumulative curve is useful representation to describe arriving and departing traffic flow. However, it should be noted that cumulative curve assumes the following two conditions.

Figure 4 Arrival curve and departure curve.

The first assumption is “First-In First-Out,” which is often abbreviated as “FIFO.” It means that an earlier arriving vehicle to the target section should depart the section earlier. In other words, all the vehicles have to keep their order of travel and there is no overtaking inside the section. By this assumption, it is possible to measure the individual vehicle’s delay by the horizontal difference of $A'(t)$ and $D(t)$ at the same height of the graph.

Another assumption is “point queue” concept, which assumes no physical length of queueing vehicles and their space clearance. In other words, arriving vehicles directly reach the bottleneck position and wait for their turn at this point for departure. It is also denoted as “vertical queue,” because the queue is represented not by horizontal formation of vehicles but by a vertical pile at the bottleneck position. Based on this concept, the shifted arriving curve $A'(t)$ means the vehicles’ arrival time at the bottleneck, and we can simply consider the delay as the separated region of $A'(t)$ and $D(t)$.

Methodologies to Measure Delay

To measure delay, travel time of a certain roadway section have to be measured. Therefore, it is basically the same as to measure travel time, that can be done various kinds of methods as follows.

(1) License Plate Matching

Setting observation stations at the both ends of the roadway section, surveyors record license plate number of passing vehicles and their passing time. It is also possible by taking video image at the observation stations. After the observation, the recorded data of the both stations are matched and then the travel time of the identified vehicles can be obtained by taking the difference of their passing time at the both stations. Although this method is easy to conduct and efficient to collect a lot of data samples, manual license plate matching is generally time consuming work. However, automated technology using image processing for license plate matching is available and makes it becomes a feasible real time solution.

(2) Measuring Vehicle Run

This method prepares a vehicle to measure travel time by running the target roadway section actually. To measure representative travel time, the measuring vehicles should travel in average speed of the traffic flow, that is, not too fast nor too slow compared with other vehicles. This method is simple and clear, however, it is difficult to collect many data samples unless many measuring vehicles and drivers are prepared.

(3) Probe Vehicle

“Probe vehicle” is an idea to utilize general running vehicles on the road network as moving sensors. Thanks to the mobile network communication technology development, it becomes possible to collect information of a lot of individual vehicles to the central server. By accumulating those information, road network condition such as speed, travel time etc. can be collected. It is also called as “floating car data (FCD).” This method requires relatively complicated and large-scale system including information transfer by communication technology. However, once the system is established, large amount and continuous information can be obtained automatically, which is very advantageous to monitor long-term transition of the performance. Another issue is privacy aspect that means drivers’ consents have to be obtained before collecting probe data.

In any methods, sometimes it may be difficult to obtain free flow travel time if delay occurs most of the time period in the target section or the section contains multiple signalized intersections. In such cases, free-flow travel time can be estimated by dividing the section length by the assumed free flow speed (e.g., speed limit).

Figure 5 A queue to buy lunchbox at street vendor.

Figure 6 Arrival and departure curve during lunchtime.

Delay as an Evaluation Index

As delay is a simple and intuitive idea that can be easily measured by recording time, it is widely used to describe the influence caused by some disturbance, such as roadwork, traffic signal and so on. In that sense, delay is a good index to evaluate queueing systems. Furthermore, total delay considers volume of users or travelers, therefore it is more appropriate to quantify the negative influence of queueing systems. Generally, smaller total delay means better performance of the system.

For example, if you would like to evaluate a certain roadwork project to alleviate traffic congestion, total delay before and after the project should be measured and the reduction of them (in other words, total travel time saving) is regarded as the effect of the project. This idea is applicable to evaluate the performance of other queueing systems that may include delay, such as highway sections, customer services, and so on.

An Example to Measure Delay Using Cumulative Curve

Here, let's see an example to measure delay by an actual queue using cumulative curves. This is not a queue of vehicles but a queue of people. A popular street vendor cooks and sells take-out lunchboxes during the lunchtime and people make a long queue to buy them everyday as shown in **Figure 5**. Now two observation points are set in the upstream and the downstream of the queue. The upstream point A is at the tail of the queue, recording the time when a new customer arrives at the tail. The downstream point B is at the vending counter, recording the time when a customer receives his/her lunchbox and leaves there.

The result is shown in **Figure 6**. Here, the cooking time which is necessary for every customer even without a queue (regarded as FFT) is already subtracted. The orange line shows the arrival curve $A'(t)$ and the blue line shows the departure curve $D(t)$. From this figure, we can understand that there were approximately 100 customers on that day. There was almost no delay until 11:53, because the orange curve and the blue curve coincided each other. After that, the two cumulative curves were separate and came close again at 12:40. That means the queue was formed during this period and the delay of a person can be measured as horizontal difference of the

two curves. The slope of the arriving curve is the arrival rate $\lambda(t)$, which varied time to time, whereas the slope of the departure curve almost stayed constant. Measuring this slope, we can evaluate the maximum service rate $\mu_{\max}$ of this vendor as approximately 2 customers/min.

The vertical difference of the two curves means the number of waiting people in the queue. The largest difference occurred at 12:13, when 32 people were waiting their turns. On the other hand, the largest delay (= the longest waiting time) also occurred to a customer arriving at this timing, that is 15 min 51 sec. Finally, the area that is surrounded by the arriving curve $A'(t)$ and the departure curve $D(t)$ is the total delay by the queue of that day and its amount was 13 hours 11 min 42 sec (man-hours). Thus, the influence of a queue can be quantified and evaluated from a simple observation, which is comparable to other cases.

G duration of green phase of traffic signal

C cycle time of traffic signal

Q_{max} maximum queue length

A queue is formed at a bottleneck when demand exceeds capacity or arrival rate is higher than service rate. Queue length is the number of vehicles/people in a queue, which shows how large a queue is. It is a very easy and intuitive way to show the size of a queue, therefore it is widely used to describe the influence of a queue or congestion. In some cases, especially when a moving queue is discussed, same number of queueing vehicles/people may occupy different spatial distance. In such a situation, queue length in physical distance would also be considered.

Definition

Queue length is defined as accumulated number of vehicles/people in the upstream of a bottleneck that joined but not yet left a queue. Therefore, to obtain the queue length, a queue itself have to be identified. Queue is a part of traffic flow whose speed is lower than the upstream and the downstream flow. The tail of the queue is the point where arriving vehicle/person join the queue, whereas the head of the queue is the point where queueing vehicle/person leave the queue. (May, 1990; Transportation Research Board, 2016)

Normally, the point queue concept is employed as shown in Chapter 10320, that is, there is no physical length of vehicles as well as their space clearance. Then, these vehicles are accumulated vertically at the point of the bottleneck and the queue length can be measured as the number of the vehicles there.

In some context, queue length in physical distance has to be discussed literally. In this case, physical queue concept is employed and queue length is defined that a queue occupies in the space from its head to its tail in the unit of distance, such as meter, kilometer, etc. The difference of point queue and physical queue is shown in [Figure 1](#). As the traffic states in queues are not always the same, the same queue length might sometimes have different influence on the performance such as travel time, etc.

Theoretical Explanation of Queue Length in Number

Similar to queueing delay in Chapter 10320, let's use cumulative curves by employing the point queue concept to illustrate queue length. We can draw arrival curve $A'(t)$ and departure curve $D(t)$ as shown in [Figure 2](#). Please refer to Chapter 10320 for the detail to draw them. If we set the current time as τ , $A'(\tau)$ means the cumulative number of vehicles that already arrived at the bottleneck and D

Figure 1 Point queue and physical queue.

Figure 2 Queue length by cumulative curves.

(τ) means the cumulative number of vehicles that already departed from the bottleneck by that time. Then, the vertical difference at this time $A'(\tau) - D(\tau)$ shows the number of vehicles remaining in the queue, that is, queue length. (Daganzo, 1997)

Theoretical Explanation of Queue Length in Physical Distance

If we consider queue length in physical distance, we need to assume not point queue but physical queue. And traffic flow characteristics in the queue such as flow rate, density, and speed should be considered. Let's see how to obtain the physical queue length using shockwave analysis. Figure 3 shows simplified vehicle trajectories that form a physical queue at a bottleneck. Each line shows a trajectory of a vehicle and its slope shows the speed of the vehicle.

Vehicles arrive from the upstream in the flow rate of λ , which is the traffic demand. However, as the bottleneck capacity is μ which is lower than λ , the flow rate in the downstream of the bottleneck is regulated to μ . And, the difference of the demand and the capacity is accumulated as a queue in the upstream of the bottleneck, whose flow rate is also μ . The vehicle speed in the queue is relatively slow compared with the upstream and the downstream section. In this figure, flow rate λ or μ can be obtained by the inverse value of time headway, which is the horizontal interval of the vehicle trajectories. On the other hand, the vertical interval of the trajectories shows space headway, which is the inverse value of traffic density.

Here, let's classify this traffic flow into three region based on their states, that is, region I, II and III as shown in different colors in Figure 4. Region I is arriving traffic from the upstream in free flow condition, and its flow rate and density are λ and k_1 . Region II is queue at the bottleneck in congested flow condition, and its flow rate and density are μ and k_2 . Region III is departing traffic from the bottleneck in free flow condition, and its flow rate and density are μ and k_3 . Then, the queue length is obtained by measuring the

Figure 3 Vehicle trajectories at a bottleneck.

Figure 4 Different states of traffic flow.

vertical distance of the region II in the upstream of the bottleneck. As the head of the queue stays at the same position, the queue length is determined if the boundary movement between region I and II is obtained.

Figure 5 is enlarged trajectories between region I and II. The slope of this boundary is denoted as u ($u < 0$). Suppose we consider a rectangular region as shown in the figure that has a unit time width t , then the height of this rectangle is $-ut$. Based on the flow conservation law, the volume of vehicles entering this unit region should exit without any loss. Then, the following equation should be established.

$$\lambda \times t + k_1 \times (-ut) = \mu \times t + k_2 \times (-ut)$$

$$\therefore u = \frac{\lambda - \mu}{k_1 - k_2}$$

Here, λt and μt are entering and exiting traffic volume from the bottom and the top edge, because λ and μ are flow rate (vehicles per unit time). Similarly, $k_1(-ut)$ and $k_2(-ut)$ are entering and exiting traffic volume from the left and the right side edge, because k_1 and k_2 are density (vehicles per unit distance). And, u shows the moving speed of the boundary, which is called shockwave. Using this shockwave speed, the position of the queue tail can be calculated and the queue length can be obtained.

Methodologies to Measure Queue Length

If the entire queue is visible from the observer, it is easy to measure the queue length in number. However, if it is not visible from one position, queue length has to be estimated by the difference of the cumulative arrival and the cumulative departure of the queue as explained in the previous section. To conduct this method, at least one traveler has to be identified both in arrival and departure to set the starting point of the cumulative curve. Another possible option is to use the traffic density inside a queue. If it is known and the queue length in physical distance is measured by the methodology as shown in the next paragraph, queue length in number is also calculated.

Figure 5 Enlarged vehicle trajectories and shockwave.

Figure 6 Arrival and departure curve at traffic signal.

To measure queue length in physical distance, the positions of the head and the tail of the queue have to be identified and recorded. Normally, the head of the queue is the bottleneck and its position is stable in many cases. On the other hand, the tail of the queue often moves a lot, therefore the observer has to follow it to record its position. It may sometimes become difficult if the tail moves quickly.

Queue Length as an Evaluation Index

Queue length is a very simple and easy way to describe how large a queue is, therefore it is commonly used in traffic information, newspapers, and so on. When some kinds of investments to improve the system were implemented, reduction of queue length would be a good index to show the effect.

In some cases, queue length in physical distance is also important. For example, when we need to design some components of infrastructure such as left/right-turn bays in intersections, storage length has to be properly designed to keep the queue inside it. Otherwise, the queue may block other traffic movements and deteriorate the system performance when its length becomes longer than that.

Queue Length at Traffic Signal

A typical case to consider queue length is commonly observed at traffic signals. Let's consider a simple traffic signal that repeats red and green phase alternately. Here, yellow phase is ignored for simplicity. The duration of red phase, green phase, and cycle time are denoted by R , G and $C(=R + G)$, respectively. Regarding the traffic flow, constant vehicle arrival rate λ and saturation flow rate μ are assumed. Suppose this intersection is undersaturated, that is, all the queued vehicles at the end of the red can leave the intersection during the next green and there is no queue when the signal turns to red. **Figure 6** shows arrival curve $A'(t)$ and departure curve $D(t)$ in this situation. $A'(t)$ has a constant slope λ , whereas the slope of $D(t)$ takes three values; zero (horizontal line) during red phase, μ during green phase until the queue disappears and λ during green phase after the queue disappears.

As explained in the earlier section, the queue length is shown as the vertical difference of $A'(t)$ and $D(t)$ in this figure. Therefore, the queue length starts to increase when red signal begins. The queue length become the maximum value (Q_{max}) at the end of red.

Figure 7 Arrival and departure curve during lunchtime.

When the signal turns to green, the queue length starts to decrease and finally it becomes zero when $D(t)$ catches up $A'(t)$. It remains zero until the end of green.

An Example to Measure Queue Length Using Cumulative Curve

Let's use the same example shown in Chapter 10320 to demonstrate how to measure queue length by an actual queue using cumulative curves. **Figure 7** is the cumulative curves obtained from the observation of the queue in front of the street vendor. The orange line shows the arrival curve $A'(t)$ and the blue line shows the departure curve $D(t)$. Then, the vertical difference of the two curves means the number of waiting people in the queue. The largest difference, that is the longest queue length, occurred at 12:13, when 32 people were waiting their turns.

Introduction

Local area traffic management (LATM) describes a range of traffic engineering measures applied to the planning and management of traffic movement in local areas (precincts or neighbourhoods). It is generally applied as remedial treatments for local street networks, usually but not always in residential precincts, which are experiencing adverse traffic impacts such as excessive volumes of traffic and high travel speeds. LATM often involves the use of physical devices, streetscape design treatments, and other measures (e.g., regulatory measures including lower speeds limits and turning restrictions), aimed at reducing through traffic movements and controlling vehicle speeds. More broadly it may be seen as a process used to plan and control the traffic usage of a local street network to achieve improvements in the residential environment of the local area, meeting goals for that end determined by relevant stakeholders.

For the purpose of distinguishing between LATM and other aspects of traffic management, a “local (traffic) area” may be taken as an area containing only local streets and collector roads, and usually bounded by arterial roads or other roads serving a significant road transportation function, or other physical barriers such as waterways, railways, reserves, or impassable terrain.

LATM implementations are usually undertaken by local government, generally and most successfully with the collaboration and involvement of community groups representing residents and local business. Neighbourhood groups concerned with pedestrian safety and traffic impacts are often the initiators of LATM plans.

Typical Traffic Problems in Local Areas

The main issues encountered in LATM studies are typically speeding, through traffic, parking, corner cutting and traffic congestion, and generally decreasing in that order of importance.

Speed management is perhaps thus an overarching concern, generally approached by the installation of midblock speed control devices (e.g., humps), but there are mixed views on the effectiveness and acceptability of different devices. For instance, speed humps are seen as effective but controversial, largely because of adverse public opinion. The effectiveness of other devices such as raised platforms, road narrowing, and kerb extensions is also widely debated. An important issue for speed control devices is their impact on buses and emergency vehicles. Some bus operators may refuse to allow buses to use road links with such devices. Alternatives such as speed cushions that permit ready bus operation may then be considered. “Blister island” treatments are also seen as an effective speed reduction device in some jurisdictions.

Table 1 lists a number of common LATM treatments and devices. The table shows two different orderings of the listed treatments, based on recent research on local government LATM practice in Australasia (Damen, 2007; Damen and Ralston, 2015). The first column lists the treatments in order of effectiveness, as perceived by municipal traffic engineers. The second column lists the treatments in terms of actual usage.

Table 1 indicates that roundabouts, installed at internal junctions in the local area street network, were ranked as the most effective device and were widely used. The second most effective device was a full road closure, but it was seldom employed.

The LATM devices expressly designed for speed limitation along a street section showed some interesting results. These devices were: flat-topped hump, road (Watts profile) hump, slow point, and speed cushion. They were ranked 5th, 5th, 13th, and 14th, respectively, in terms of effectiveness, but there was clear evidence of a growing reluctance by municipalities to use them. Less than half of the surveyed authorities rarely or never used flat-topped humps, Watts profile humps or slow points. The speed cushion is perhaps a more specialized installations only suited to specific cases (e.g., cater for bus movements along a street). The Watts profile hump was found to be the least popular in the community, with three times the level of complaints received about the next most unpopular device, the flat-topped hump. Most other devices appeared to attract little or no complaint.

Table 1 LATM devices employed by local government in Australasia, listed in terms of effectiveness and usage

<i>Effectiveness of treatment (most effective to least effective)</i>	<i>Usage of treatment (most common to least common)</i>
Roundabout	Roundabout
Full road closure	One way, stop and give way signs
Median treatment	Lower speed limit
One way, stop and give way signs	Kerbside lane narrowing/kerb extension
Flat top road hump	Median treatment
Blister island	Blister island

Good Practice

Good practice in LATM applications may be taken as the formulation of LATM policy specifically aimed at:

1. maintaining amenity in local, residential access streets by deterring inappropriate levels of through traffic from using those roads and controlling the speed of traffic that does use them;
2. recognizing the varied uses of the road space and optimizing the safety and viability of using walking, cycling or public transport as alternatives to the private car; and
3. determining the circumstances in which traffic calming works are warranted and prioritizing them equitably to address the aims 1 and 2 above.

The need for LATM investigations should then be triggered by the observation that one or more of the following factors exceeds acceptable limits:

- speeding (85th percentile speed greater than the relevant speed limits of, for example, 40, 50, or 60 km/h);
- volume (annual average daily traffic, considered in relation to surrounding streets);
- through traffic (which is to be considered in the context of the total traffic volumes); and
- safety (examined through consideration of crash statistics, street geometry and roadside environment, and identified risks).

Data collection and assembly for the previous factors provide basic information on the likely extent of traffic problems facing a given local area.

Barriers to implementation may exist. In particular strong community support is vital. Sometimes local residents may be opposing to a LATM scheme, often relating to the suggested use of specific types of LATM devices rather than an overall concept plan. Strong local community support is essential for the success of a LATM scheme, so that community participation in the planning and design of LATM and the compatibility of a proposed scheme with local aspirations and objectives is essential. Financial costs may be an issue for some municipalities. Historically, some traffic engineers objected to LATM plans when concerned about traffic mobility rather than overall street design.

LATM Design Solutions

LATM is applied to an area through the use of physical devices, streetscaping treatments, and other measure (including regulations to influence vehicle operation on local streets), in order to create safer and more liveable local streets. The basic concept for good LATM design can be summarized by the following rules:

Figure 1 Traffic rush on two streets, one with resident complaints about traffic problems, the other with no complaints.

- good local street design should aim for *poor long distance visibility* (for visual enclosure) but *good short distance visibility*, especially between knee and head height;
- devices should be forgiving on those drivers who misjudge them, for example, solid immovable objects should be set back well behind deflective kerbs;
- construction materials, road geometry, and texture should indicate the local nature of the street and its multiple use;
- good night time visibility is critical, especially for strangers to the area; and
- *the more local the street, the greater the importance of landscape architects and urban designers*. They, rather than the traffic engineer, should have the major say in the design of devices in streets, which carry less than 2000 veh/day.

One useful parameter indicating the potential susceptibility of a street to local traffic problems is its “traffic rush.” A traffic rush metric (rush per hour) may be defined as the sum of the speeds of all vehicles passing in an hour, in either one direction of interest, or in both directions as a measure of total disturbance from passing traffic (Woolley et al., 2002). Fig. 1 shows contrasting traffic rush patterns for two different streets in one suburb (following the introduction of the 40 km/h local area speed limit in that area). One of the streets had complaints voiced by local residents—it attracted rush hour traffic from a nearby crowded collector road. The second street had no specific complaints raised about traffic. The contrast shown in Fig. 1 for the problem street between morning rush hour and the rest of the day is significant. While the total rush on the other street (the total rush on a street is shown by the area under the traffic rush curve) is greater than that on the problem street, the rush hour contrast to 9:00 a.m. is far less, by a factor of at least six, that is, the contrast is far less pronounced on the transverse street.

The concept of speed-based design, in which the geometric features of the street and its road pavement are adjusted to provide a driving environment that encourages lower traveling speeds by vehicles, is now seen as the primary design tool for LATM. This approach is less concerned with the use of specific speed control devices, but rather seeks to ensure an overall street speed environment, which is compatible with community expectations. It involves flattening the speed profile of the street, that is the variation of free speeds along the street length. The speed management objective is then given as a target speed profile. The speed profile is the graph of instantaneous vehicle speed along the street. Fig. 2 Fig. 2 shows an example of the “before and after” speed profiles along a street from which humps were removed and a roundabout then installed. The two speed profiles represent the actual traversal of a length of local street by a vehicle, which runs in to the street from a main road and travels some 800 m along the street, to exit it at a stop sign. In the “before” case the street contains seven Watts profile humps, approximately 100 m apart. In the “after” case, the humps have been removed and a single roundabout installed at an intersection about 300 m from the entry point. The data presented in Fig. 2 are based on actual observations of traffic movement on the street in question (Zito and Taylor, 1996).

The “before” speed profile in Fig. 2 shows a succession of decelerations and accelerations as the vehicle negotiates each hump in turn, with the driver attempting to regain a cruising speed of about 45 km/h between the humps. This leads to a confusing speed

Figure 2 Comparison of speed profiles before and after the removal of road humps.

environment as the instantaneous speed of the vehicle is changing continually. In the “after” case, the speed profile is more stable, with a single deceleration and then acceleration as the vehicle negotiates the roundabout.

Speed management should therefore aim to lower the speed profile based on a realistic estimation of driver behavior. It requires consideration of the sequence of speed control devices along the street, not each device in isolation. Each device can be assumed to have a “zone of influence,” the distances either side of the device where the traversing vehicle’s speed is affected by the device (Taylor and Rutherford, 1986). These zones of influence can be seen in Fig. 3. Figure 3 indicates the ‘zone of influence’ and the speed differential for a speed control device. Note that the design speed variable for the speed profile is the 85th speed, that is, the speed exceeded by 15% of the vehicles traversing the street section where the device is located. Outside the zone of influence, drivers will try to maintain their free speeds, whatever the speed at which they have to traverse the speed control device itself. The aim of speed-based LATM design is thus to ensure that the new street speed is below a target speed and thus minimize fluctuations in speed along the street. This may be accomplished by considering the “speed differential,” which is the difference between free speed and the traversal speed of the device at that point—with all other treatments in place. A maximum value for the speed differential of 20 km/h is recommended.

The speed differential can then be used to select, design, and locate the sequence of devices along a street. High-speed differentials imply large speed changes within the zones of influence and thus along the length of the street, with consequent risks of increased noise and hazard.

The speed-based design process is summarized by the following steps:

1. measure or estimate current free speeds on the street section;
2. specify target street speed, and thus the required speed differential; and
3. design the scheme to meet the target speed with speed differential below the maximum allowed value at each device in turn.

There is a wide range of traffic control devices available for use in LATM. Table 2 indicates the application of different devices and identifies them according to the device categories defined by Ogden (1996):

1. regulatory devices,
2. network modifications,
3. intersection devices,
4. vertical displacement devices,
5. horizontal displacement devices, and
6. gateways.

Fig. 4 illustrates some of these devices.

Figure 3 The “zone of influence” and the speed differential value for a speed control device such as a road hump.

^aFor traffic driving on the lefthand side of the road, as in the United Kingdom, Australia, Japan, India, and New Zealand (amongst others)

Observations of traffic behavior on local streets suggest that the more devices that are installed along a street, the milder the effects of each device (in terms of speed differential) need to be. At the limit, the least speed differentials will be obtained on streets with continuous speed control devices. One continuous speed control device is the use (and enforcement) of lower speed limits.

(A) Lower speed limit, area-wide

(E) Flat top hump

(B) Street closure

(F) Slow point

(C) Roundabout

(G) Blister island

(D) Road (Watts profile) hump

(H) Left in/left out gateway

Through Traffic

Besides excessive speed, through traffic intrusion is also a recognized traffic issue for traffic precincts. Local traffic, being traffic with either or both an origin and a destination in the area, would be considered to be part of the area and its activity and more likely to behave in ways compatible with the local street environment in terms of speed, and would therefore be seen as an acceptable part of the local life.

Figure 5 Road hierarchy classification, including the classical and functional conceptual models of the split of traffic movement and site access functions for the road classes.

The issue is to consider what actually constitutes through traffic, either in a local area or on a particular street section. For example, the objectives of an LATM study can be to:

- reduce vehicle speeds in the area;
- reduce through traffic volume on local streets and encourage it to use more appropriate roads, and
- effectively manage on-street parking in areas in which this is a problem.

A common definition of through traffic is “traffic with neither an origin nor a destination within the local area. Depending on the definition of the local area, this may not be traffic which diverts between two arterial roads.” This definition includes the possibility that traffic originating in one part of a local area may in fact be seen as through traffic in another part of it. However, the definition is not particularly useful in assessing the extent of this issue. What it does provide is the indication of a longstanding principle in LATM that local streets should only be available for the terminal ends of journeys and for local circulation and access, and not be regarded as a part of the general urban road transport network. This principle is embodied in the concept of the hierarchy of roads in which roads are classed in terms of their traffic-carrying or access functions, with local streets serving a predominant access function. A typical urban road hierarchy would include the following road classes: urban freeways, urban arterial roads, subarterial roads, primary collector roads, secondary collector roads, and local streets. The freeway is solely for traffic movement. The ultimate local street, which can provide no more than access, is a cul-de-sac. All other road classes involve some proportioning of traffic movement and site access function. **Fig. 5** indicates the conceptual differences in traffic function (movement or access) between the road classes. Note that this figure presents the both the historical “classical” view of a continuous change in function proportion between the road classes, and the more recent “functional” classification which suggests a break between access and movement, for the case of collector roads. The functional classification model is based on the observation that network design including roads which attempt to provide an even balance between movement and access generally fail to provide satisfactory service for either function on those roads.

The hierarchy of roads may be used to suggest a definition of through traffic that can be applied across a study area including the level of the individual street (**Brindle, 1989**). The idea is that of an “ideal” journey structure for a vehicle moving from its origin, as directly as possible, via increasingly “important” roads (in traffic-carrying terms), until it reaches the arterial road network on which the principal part of the journey takes place. If the destination is in a local street, the vehicle then moves back down the road hierarchy, only entering the local access road network when necessary. Thus, in the ideal journey, traffic moves upwards then downwards in the road hierarchy, so that it minimizes the length of travel in the local access street network. It follows that through traffic is traffic which, on some part of its journey, has dropped down then goes back upwards in the hierarchy. Traffic which, for whatever reason, has dropped down sooner into the “lower-order” network so that length of travel on those roads is greater than the minimum is also through traffic on that part of its journey, even if the route choice is logical to the driver. **Fig. 6** summarizes this definition of through traffic.

This figure identifies an “ideal” journey through a network, which minimizes the use of the “lower-order” roads in the hierarchy, and a hypothetical “rat running” trip in which a through vehicle penetrates a residential area. Through traffic is thus any traffic movement involving the use of a lower class road section in mid journey. American studies of traffic precinct design have suggested

Figure 6 Definition of “through traffic” in terms of the usage of different classes of roads in the road hierarchy, including an “ideal” journey and a “rat running” journey. Source: Adapted with permission from Brindle (1989)

that the maximum driving time required to reach a collector road from any address on a local residential street should be one minute (Ewing, 1999), as a means of encouraging drivers to use the “higher class” roads for the bulk of their journeys.

Critical Values

While there is no established “best” practice for setting warrants or priorities for LATM implementations, there are a variety of mixed systems of warrants, priority rankings based on aggregate points scores on a set of traffic factors, and accepted “threshold” values. Points scores for priority rankings may be based on both objective (observed data) values and subjective values, using expert opinion or the results of community surveys. These are likely to be particular to specific communities at given points in time, so there can be no firmly established values for general use. However, the reported values may be used in an indicative fashion when considering the likely severity of perceived or actual traffic problems in local areas.

Typical factors for inclusion in a rating system include:

- character and function of the street,
- general speed limit.
- traffic volumes and speeds,
- level of “nonlocal” traffic,
- level of commercial traffic,
- presence or absence of major traffic generators or non-residential users,
- availability of crash data or safety review inspection assessments,
- availability of lighting, and
- degree of local support.

Note that some factors may interact, so that an adjustment in one factor may change the level of acceptability of another. Traffic speed and volume are a case in point, where the combined effect may be the key driver to the development of a traffic problem and to its resolution. For example, a local street carrying more than 2000 veh/day with an 85th percentile speed of 55 km/h is likely to have a traffic problem, whereas if the 85th percentile speed were 45 km/h the likelihood of there being a recognized problem would be significantly reduced.

A particular concern for some LATM studies is the possible level of through traffic intrusion in the area, largely concerning “rat running” behavior through a local street grid, or access to specific traffic generators located on the periphery or nearby the study area and for which access (including parking in the study area) may be sought through the local area.

One “rule of thumb” is that if the peak hour traffic volume exceeds 15% of daily total traffic then there is a strong likelihood of “rat running” behavior in the street, implying the presence of through traffic. This percentage could be taken as a trigger value. It can also be related to the “traffic rush” metric (Fig. 1).

On the basis of the functional model for road classification under the hierarchy of roads and using recent research results, the set of threshold values in Table 3 can be suggested.

The threshold values in Table 3 may then be taken as triggers to alert the traffic engineer to the possibility of speed or volume-related traffic problems on a particular street or road section.

Table 3 Recommended threshold values as a guide to identifying traffic problems in a local area

Threshold value	Sub arterial	Primary collector	Secondary collector	Local street
1. Minimum traffic volume: daily traffic	>9000 veh/day	>6000 veh/day	>3000 veh/day	>1000 veh/day
peak hour traffic	>900 veh/h	>600 veh/h	>300 veh/h	>100 veh/h
2. 85th percentile speed	5 km/h above speed limit	5 km/h above speed limit	5 km/h above speed limit	Above speed limit
3. Anticipated through traffic (from origin-destination data, if available)	65%	60%	40%	25%
4. Peak hour factor	>15%	>15%	>15%	>15% or >15 veh/h ^a

^aFor very low volume streets, the percentage value is less useful and a component traffic volume is a better guide, hence a combined threshold value for local streets is more appropriate.

Conclusions

LATM involves the planning and management of road space usage in a local traffic area, often to modify streets and street networks which were originally designed in ways that are now no longer considered appropriate to the needs of residents and users of the local area. LATM can be seen as a tool of traffic calming at the local area (precinct) level. It involves the use of physical devices, streetscaping designs and treatments, and other measures (including regulations and other non-physical measures) to influence driver behavior, with the aim of creating safer and more pleasant streets in local areas.

LATM is system-based and area-wide. It considers neighbourhood traffic-related problems and their proposed solutions in the context of the local area or a group of streets within it, rather than only at isolated locations. In addition, it requires that physical traffic management measures be seen as a sequence of interrelated devices rather than individual treatments. Traffic engineers need to be alert to the potential problems of isolated speed management devices.

The primary target of LATM is to change driver behavior, both directly by physical influence on vehicle operation and indirectly by influencing the driver's perceptions of what is appropriate behavior in that street. The objective is to reduce traffic volumes and speeds in residential areas to improve amenity, increase liveability, and improve safety and access for pedestrians and cyclists.

The need for LATM usually arises from:

- an intent to reduce traffic-related problems,
- orderly traffic planning and management,
- a need to modify "transport" behavior,
- a desire to improve the community space,
- a desire to improve environmental, economic and social outcomes,
- traffic interventions associated with new development or the implementation of pedestrian and bicycle plans and other local policies.

Traffic-related problems concern mainly:

- improved traffic safety and security, leading to programs for speed moderation and other changes in driver behavior; and
- protection or improvement of local amenity focusing on appropriate allocation, design, and use of street space, as well as driver behavior.

The following planning and design principles, which help to build and ensure attractive streets and healthy communities, should therefore be applied in LATM implementations:

- build the street for everyone, for streets have multiple uses that must be recognized and balanced;
- create many linkages so that pedestrians and cyclists have multiple routes to destinations;
- provide comfortable footpaths, and streets that are easily crossed;
- keep motor vehicle traffic dispersed and moving at low speeds;
- tree planting and landscape design help to foster the attractiveness of a street;
- ensure the presence of public space, for the street is a main component of the public realm in which people and interact and build community spirit; and
- build to a proper scale and size, focusing on people not motor vehicles.

Influencing Mechanism of On-Street Parking on Dynamic Traffic Flow

The concern about the interference of on-street parking on dynamic traffic flow has been longstanding and pervasive. Relevant study involves parking search and traffic flow theory. Before the 1980s, scholars studied the traffic operation and safety problems caused by on-street parking. Before entering the 21st century, the influencing mechanism of on-street parking on dynamic traffic is still in its infancy. Scholars were still focusing on basic traffic flow theory. The development of traffic flow theory and models has gone through a process from free flow theory to non-free flow theory, then to mixed urban traffic flow theory. In this stage, a lot of discussions have been made on which forms (parallel, vertical and oblique) of the parking lot should be setting in the road. For many years, traffic engineers believed that parking along major roads should be prohibited at least during rush hours, while angle parking can only be set on low-speed roads. Since 2000, the research on this issue has become multi-objective. More research emerged with the focuses on improving road safety and operation efficiency, reducing delays, considering stakeholders, setting on-street parking belts, achieve the comprehensive optimization of overall social benefits (Zhenyu and Jun, 2012). Automatic parking system is another new research focus. Algorithms has been designed for vehicles to park in existing parking spaces automatically, while the design methods of on-street parking spaces have not been updated for automatic driving.

Supply Allocation

Considering that unreasonable supply allocation of on-street parking lots (parking spaces scale, location layout, and the spatial design of parking spaces) will occupy urban road space (motor lane, non-motor lane, and pedestrian passage), and then affect urban traffic flow operation, it is necessary to study the supply allocation methods of on-street parking lots.

Parking Spaces Scale and Location Layout

Supply allocation (parking spaces scale and location layout) of on-street parking lots is closely related to road conditions, so the influencing factors of supply allocation mainly include road conditions and road network gradation, road network capacity, traffic conditions and road network service level, off-street parking facilities, and traffic management level.

The parking supply analysis of on-street parking mainly includes the determination of capacity and location. Among them, the determination methods of parking capacity can be summarized into three types: (1) the determination method based on user travel cost; (2) the threshold determination method based on multiple constraints; (3) the determination method based on stochastic gap theory and queuing theory. The location determination of on-street parking is mainly based on the establishment of multi-level and multi-objective optimization model, which comprehensively considers the impact of on-street parking on dynamic traffic, detour distance, walking distance, and spaces supply.

However, considering that on-street parking spaces around different types of buildings (schools, residential areas, offices, shopping malls, etc.) often show different parking demand in different time periods, there are few research results about the supply allocation of on-street parking spaces in different time periods. Therefore, in the future, different parking supply allocation strategies (parking spaces scale control, parking time limit, parking guidance, etc.) should be researched and implemented to avoid illegal parking in the peak hour and waste of resources in the off-peak hour according to different on-street parking demand.

Spatial Design Method of Parking Spaces

Each country has proposed spatial design methods of on-street parking spaces according to its own actual situation. China's "Setting Specification for Parking Spaces in Urban Road (The Industry Standard of Public Security, 2009)" gives general requirements, setting

conditions, road sections and areas where parking spaces should not be set, and design methods of parking spaces on urban roads, the design layouts of Chinese on-street parking spaces are shown in Fig. 1 (The Industry Standard of Public Security, 2009). Rochford District Council's "Parking Standards Design and Good Practice Supplementary Planning Document" also gives a variety of parking styles including Square Parking (or 90° Square Parking), Angled Parking, Parallel or "End to End" Parking, as shown in Fig. 2.

The following conditions should be considered in the design of on-street parking spaces: (1) road conditions, involve road width and cross-sectional form; (2) traffic volume conditions, involve motor vehicle flow, non-motor vehicle flow and pedestrian flow in the section; (3) rationality of the planning location, involves coordination between parking belts on road and road environmental conditions such as signalized intersections, road openings, and pedestrian crossings.

In the future, with increasingly serious environmental problems, the design of on-street parking spaces needs to be considered as an important aspect. In addition, with the rise and promotion of automatic driving technology, the research of on-street parking spaces design method will certainly face changes. Since computer-controlled vehicles could perform more stably and accurately than human drivers in parking process. And it can be assumed that the interference of on-street parking on traffic flow can be reduced to a certain extent through the communication and cooperation between vehicles.

Figure 1 Design layout of Chinese on-street parking spaces (GA/T850-2009).

Parking Supply and Demand Regulation Strategies

If the urban on-street parking resource is not under management, more drivers will park in on-street parking lots for a long time or illegally park on urban roads and pedestrian passages, which deviates from the positioning function (temporary short parking) of on-street parking lots, seriously interferes with urban motor vehicle flow, non-motor vehicle flow and pedestrian traffic, and affects the urban landscape. In order to maximize the utilization of parking resources in limited land, some scholars and relevant urban management departments discuss the regulation of on-street parking demand from two aspects: parking demand regulation strategies and parking supply regulation strategies.

In terms of parking demand regulation strategies, they mainly rely on law enforcement management, parking pricing policy, and management of supply-demand relationship to regulate on-street parking demand. There are different measures to increase the turnover of on-street parking. For example, parking rates increase exponential with the duration of parking. **Fig. 3** is one of such examples to discourage long-term parking. As for parking rates, the parking demand, the parking price of off-street parking lots, the parking spaces occupancy and other factors should be comprehensively considered to determine the pricing standard of on-street parking lots. San Francisco has introduced the "SF Park," which are sensors installed on parking spaces to detect when the parking spaces are occupied, and formulates parking prices based on the data of parking spaces in various regions, so as to control on-street parking demand (**Chatman and Manville, 2014**). Analogously, the utilization rate of parking spaces in different blocks were investigated in Seattle to find the optimal parking price. (**Pu et al., 2017**).

In the aspect of parking supply regulation strategies, the supply strategies are mainly carried out on the premise of ensuring the level of road service (traffic flow and running speed) and reducing network congestion, including determining the maximum supply scale of on-street parking spaces, the parking time limit, etc. There are also some schemes to prohibit on-street parking during peak period and parking is only allowed during off-peak and/or inter-peak periods, as shown in **Fig. 4**.

Considering the air and noise pollution caused by on-street parking, the impact on ecological environment should also be taken into account when setting parking supply and demand regulation strategies. In addition, future parking supply and demand regulation strategies (parking price adjustment, parking spaces scale adjustment, and parking time adjustment) should be dynamically implemented according to real-time parking demand prediction results and traffic flow condition of road network. At the same time, parking spaces utilization information collected by intelligent multi-source big data (GPS, video, vehicle network, and other data) can be used to analyze the impact of dynamic regulation strategies on the on-street parking demand, and then the effectiveness of dynamic regulation strategies can be evaluated.

Intelligent and Informational Parking Management

With the rapid development of smart phones, parking information monitoring and communications media, more parking information services (e.g., vacancy information inquiry, parking space reservation, parking guidance, self-service payment, charging of

Figure 4 Prohibit on-street parking during peak period.

new energy vehicles, etc.) and parking resource management demand have been derived, and a lot of parking Apps and intelligent management system or platform has accordingly appeared. The parking App mainly serves drivers, the intelligent management system or platform mainly serves relevant management departments.

The premise for the parking Apps companies to enter the market is to establish a cooperation mechanism with the managements of parking resource (e.g., government, the operator of the parking lot), so as to obtain the real-time parking information (the number of remaining parking spaces, charging information, etc.) of parking lots. The real-time information of on-street parking lots is generally obtained by the geomagnetic detector, high-level video detection equipment, etc. The real-time information of off-street parking lots is generally obtained by the access control system, etc. After that, the background system of the parking Apps transforms the real-time parking information into visual information which is released to the driver through the interface of parking Apps. The relevant information includes the real-time number of remaining parking spaces (Fig. 5), parking charge information (Fig. 6),

Figure 5 The real-time number of remaining parking space (APP: PP Parking).

Figure 6 Parking charge information (APP: park opedia).

Figure 7 Electric vehicle charging station (APP: PP Parking).

electric vehicle charging station (Fig. 7) and other information of the parking lots near the destination. When the driver selects a parking lot, some Apps can provide the services of parking space reservation (Fig. 8) and parking path navigation (Fig. 5). When the driver arrives at the parking lot, some Apps can also provide the service of indoor navigation (Fig. 9). When the driver leaves the parking lot, the parking fee can be paid to the parking APPs by swiping the card, scanning the code (Fig. 9) and unconscious pay. The key to the development of parking App is to get enough parking resources as much as possible.

Parking intelligent and information technology can not only serve the driver, but also facilitate the management of parking resources by relevant parking departments. On the one hand, it is necessary to improve the standardized management of parking behavior on the on-street parking lots, such as collecting evidences of fee evasion and vehicles scraping, etc. On the other hand, excessive utilization of on-street parking resources will interfere with dynamic traffic flow, relevant management departments also hope to use intelligent on-street parking management system or platform to timely release parking information and road traffic information to drivers, facilitating drivers to make decisions (choose the off-street parking lots, change the travel mode, etc.) as well as maintaining a good on-street parking order.

Figure 8 parking space reservation service (APP: park mobile).

Figure 9 Indoor navigation service (APP: PP Parking).

However, due to the reality that parking information of all kinds of parking facilities (on-street, off-street, and building accessorial parking lots) is not shared, uncritical on-street parking control, drivers' parking preference and other reasons, too many drivers still choose on-street parking or illegal parking on roads, result in low utilization of off-street parking resources. Therefore, in order to make full use of the overall parking resources of the city, an urban intelligent parking platform integrating on-street, off-street and building accessorial parking lots should be constructed. The parking availability information of various parking lots should be timely released to drivers so as to facilitate drivers to make parking decisions and improve parking convenience. Thus, the social and economic benefits of urban parking facilities resources will be improved.

Parking Supply Allocation

Off-street parking lots occupy a large amount of urban space resources, and unreasonable supply allocation of off-street parking lots will result in a waste of parking resources. Therefore, it is necessary to rationally determine the supply allocation of off-street parking lots (parking spaces scale, location layout) based on parking demand prediction theory and parking supply theoretical method.

Parking demand prediction theory is one of the basis for determining the parking spaces scale of off-street parking lot, it is mainly based on the parking spaces utilization characteristics of different types of land in different periods of time (working days, weekends, and peak or off-peak parking periods of a day), parking demand influencing factors, parking behavior characteristics (vehicles arrival and departure, parking time, parking times, etc.) and parking management strategies (parking sharing, etc.), and to comprehensively analyze the parking demand of all kinds of land-use within the influence scope of the off-street parking lot.

On the basis of research of parking demand prediction theory, some scholars and relevant management departments further consider extra factors such as urban parking management strategy (zonal differentiated parking supply, etc.), the interaction mechanism between dynamic and static traffic. They put forward theoretical methods of parking supply for off-street parking lots, including determining the parking spaces scale and location layout.

In terms of the determination method of parking spaces scale, there are differences between building accessorial parking lots and public parking lots. For building accessorial parking lots, the main research contents are establishing principles and methods of parking requirement standard. Before 1970s, large cities in Europe, America, and other countries built parking facilities in strict accordance with the minimum requirement standard of off-street parking facilities. After 1990s, the parking requirement gradually changed to the highest standard (Weinberger et al., 2010). At present, according to the concept of "zonal differentiated parking supply", some cities in China have formulated differentiated parking requirement standards for different types of buildings in different zones. When calculating the reasonable parking spaces scale of public parking lots, many factors should be considered, such as parking demand, parking management strategy (parking spaces control index of public parking lots, zonal differentiated parking supply), city's socioeconomic attributes (population, motor vehicle ownership, etc.), urban land development and utilization condition, urban traffic development strategy, the interaction mechanism between dynamic and static traffic, etc.

For the determination method of the location layout of off-street parking lots, the main optimization objects involve public parking lots and P + R (Park-and-Ride) parking facilities. For public parking lots, the restrictions such as parking land, the impact of location layout on dynamic traffic and drivers' travel cost (driving distance, walking distance) are mainly considered. For P + R parking facilities, location layout optimization focuses on combining with urban traffic transfer hubs, the optimization goals are to minimize the park-and-ride cost of users and improve the utilization of urban traffic transfer hubs (Farhan and Murray, 2008; Aros-Vera et al., 2013). At present, the research on the coordinated layout optimization of multi-type parking facilities is relatively weak, such as the coordinated location optimization of on-street and off-street parking facilities.

Management Strategy

Off-street parking lots occupy huge urban space resources and require high construction and maintenance costs. In order to give full play to the social benefits (meeting parking needs, ensuring a certain proportion of parking spaces occupancy rate or turnover rate) and economic benefits (parking operation income) of off-street parking lots, some management strategies need to be adopted to improve the parking spaces utilization of off-street parking lots. On the one hand, the parking profits can be realized by setting

reasonable parking charges in order to ensure stable customer flow and orderly parking of vehicles. On the other hand, through parking sharing measures, the vacant parking resources can be activated, and the parking resources in the areas can be fully utilized over different period of time.

Parking Charging Research

When the parking costs of off-street parking lots exceed on-street parking lots, drivers will cruise to urban roads for an on-street parking space. Since cruising can affect dynamic traffic, many researchers have estimated that on-street cruise vehicles account for about 40% of the total traffic volume in some neighborhoods (Garrett, 2014). When the parking costs of off-street parking lots are lower than on-street parking lots, drivers will not be motivated to look for an on-street parking space. However, low income can hardly improve the economic benefits of off-street parking lots, and also lower the enthusiasm of social capital to invest the construction of off-street parking lots. Therefore, it is necessary to develop a reasonable pricing system for off-street parking lots to improve the efficiency of parking resources and the economic benefits of parking lots.

The influencing factors for off-street parking prices mainly include the comprehensive costs, economic incentives, economic affordability of drivers, relationship between parking supply and demand, on-street parking prices, parking time, and parking policy. In addition, the parking price is inseparable from the type of off-street parking lots. With regards to the pricing target of public parking lots, maximization of the multi-party benefits (drivers, investment operators, and parking management departments) is considered to achieve parking convenience, market development, and traffic management; whereas for the industrial investment parking lots, the most important consideration is the maximization of economic benefits. Due to the high-investment costs of off-street parking lots and the long cycle of capital recovery, scientific operation, development mode, and subsidy method will become the research focus; the low charge of P + R parking facilities mainly attracts park-and-ride drivers to use public transport to achieve the purpose of traffic management; the pricing standard of building accessorial parking lots for parking sharing mainly considers the balance of interest between parking spaces owners, users, and operating companies. In the future, based on the analysis of impact of dynamic parking charges on parking demand and benefits through intelligent multi-source big data, solving the dynamic optimal parking pricing will be a hot issue.

Parking Sharing Research

In recent years, with the rapid increase in car ownership in cities, limited-parking facilities can no longer meet the growing demand for parking. In view of this, a number of scholars and relevant urban management departments have proposed alleviating the contradiction between parking supply and demand by sharing parking resources. The main feature of parking sharing is the dynamic matching of parking resource supply and parking demand for various purposes by opening the parking space use authority (permit) while not changing the total supply of parking spaces in the area and ensuring the primary demand of parking in the various buildings. In order to implement parking sharing, it is necessary to research parking sharing resource allocation and parking sharing management policies.

The allocation of shared parking resources is determining the type of shared parking facilities, the number of shared parking spaces, and the opening time windows by using space-time technology and optimization model. In the above process, the matching degree of parking supply and demand, the sharing willingness, the travel characteristics of parking users and the sharing economic benefits should be considered. In order to promote the development of parking sharing policy, some relevant departments and scholars have carried out research on parking sharing management measures, including the development of universal parking spaces sharing step, the establishment of parking sharing system (management and supervision subjects, operating mode), gradual reduction or elimination of the parking spaces in the surrounding roads, and determining the cost of parking sharing and the number of reserved parking spaces. The above research may provide a theoretical basis for relevant departments, operating companies to purchase shared parking spaces, analyze customer groups, and formulate operational management strategy.

Intelligent and Informational Parking Management

The off-street parking lots' parking spaces status have time-varying characteristics, and the large parking lots have a large number of parking spaces and a complex spatial structure. In consideration of the parking guidance needs of drivers in the above scenarios, it is necessary to investigate the relevant parking guidance information technology. In addition to the rapid development of vehicle equipment, smart phones, parking supply and demand information identification, matching and transmission technology, more parking information services (information inquiry, parking guidance, parking reservation, self-service payment, etc.) have been derived. In order to make it convenient for drivers to enjoy diversified parking information services, it is necessary to build parking information service platform. With the development of new automotive industry (driverless technology, time-sharing rental vehicles, new energy vehicles, etc.), the parking demand of new automotive industry needs to be addressed through advanced technical means and model algorithm.

Parking Guidance Information Technology

Drivers often need parking guidance information during travel and arrival of large parking lots: (1) Before or during the travel, drivers often choose an appropriate parking lot around the destination based on their parking preferences (acceptable maximum driving distance, walking distance, charge, etc.), road congestion, and other factors. However, the availability of parking spaces in the parking lot has time-varying characteristics, and drivers need to know about availability information of parking spaces during the travel, in order to make timely decision (continue to drive, change parking lot, park-and-ride, etc.) to prevent parking failure; (2) When drivers arrive at a large parking lot, due to the large number of parking spaces and the complex spatial structure, it is necessary to use parking guidance information to induce vehicles from the entrance to the appropriate parking space and to provide the function of searching vehicles reversely. Considering the drivers' parking guidance information demand in the two travel stages, it is necessary to research the parking guidance information technology in corresponding stage.

1. Parking guidance method in the travel

Urban Parking Guidance Information System (PGIS) can provide accurate and real-time information on parking spaces for drivers in the travel phase. At the same time, PGIS can balance the spatial-temporal distribution of parking vehicles in various urban parking facilities, and make full use of urban parking facilities. The VMS (Variable Message Sign) design is the main research content of PGIS, consisting the research on information release and location selection. In the aspect of information release, as the remaining parking spaces have time-differentiated characteristics, it is necessary to predict the number of vacant parking spaces in a short period of time in future, and release relevant information to drivers through VMS to facilitate drivers to make reasonable decisions (continuation of driving, change parking lot, park-and-ride, etc.) in accordance with their travel time. In terms of location selection research, the VMS location scheme should be comprehensively identified from the perspectives of vehicles guidance demand, VMS service level and operation effect, road network traffic flow, system investment, and environmental impact.

2. Vehicles guidance and other service functions in large parking lots

In order to better realize vehicles guidance in large parking lots, it is necessary to accurately judge the occupancy status of each parking space, and then transmit the parking space status information to the management system. The management system assigns parking spaces and recommends paths to drivers. Furthermore, large parking lots should provide reverse parking search service to guide drivers to walk from the pedestrian entrance to their parking spaces and exit to leave the parking lot. At present, the status recognition of parking spaces, guidance of vehicles and pedestrian paths and other service functions (real-time monitoring, parking charge, parking information inquiry, intelligent anti-theft protection) can be achieved through geomagnetic sensors, RFID (Radio Frequency Identification Devices) technology, image recognition, RSU (Road Side Unit) technology, map matching algorithm, and other technologies.

Parking Information Service Platform

VMS is a relatively traditional parking guidance technology. However, with the rapid development of vehicle equipment, smart phones, parking supply and demand information identification, matching, and transmission technology, more complex parking information service platforms have been formed. The parking information service platform can provide multiple parking service information (vacancy, reservation, guidance, and charging) through the Internet, Internet of Things, Vehicle Network, and other media, and realize more convenient and intelligent parking service. For example, [Safi et al. \(2018\)](#) proposed a parking information system based on cloud platform, which provides parking information and reservation services to drivers, taking into account driving and walking time, traffic congestion, and other factors.

However, based on the parking survey of some cities in China (Wuhan, Xiamen, Nanjing, and Shenyang), there are differences in the management departments of different types of parking lots (off-street, on-street, and building accessorial parking lots). Different types of parking lots belong to the government or private property, so the government can not integrate all kinds of parking lots' parking information (parking spaces utilization status, parking charge, etc.) into the parking information service platform. In order to further enhance the balanced use of different types of urban parking resources and the convenience of drivers, relevant management departments should adopt administrative means, incentive mechanisms, tax policies and other measures to integrate all kinds of parking lots into the parking information service platform, giving full play to the social and economic benefits of urban parking resources. In addition, the current parking information service platform mainly serves traveling individuals and parking lots operators, and the future service functions should also serve the government and related industries, such as the realization of location tracking, alarm for special vehicles, and providing basic data for the coordinated management of dynamic and static traffic.

Parking Support Technology for New Automobile Industry

With the development of new automobile industry (driverless technology, time-sharing rental vehicles, new energy vehicles, etc.), it is necessary to solve the parking demand of new automobile industry through advanced technical means and model algorithm. For driverless technology, the future system framework of intelligent parking lots should consider the parking process, parking rules,

parking demand of driverless vehicles and coexistence mode between traditional vehicles and driverless vehicles, and design an driverless module which integrates parking demand response, vehicle access control identification and parking space allocation. For time-sharing rental vehicles, it is necessary to consider factors such as vehicles rental demand, the convenience for users to pick up and return vehicles, vehicle scheduling strategy, etc., so as to determine the location layout and scale of time-sharing rental parking lots. For new energy vehicles, we need to consider the parking and charging demand of vehicles, the increasing trend of the number of new energy vehicles and other factors, and discuss the location layout of charging piles in the city, as well as the scale standards of charging piles in different zones and different types of parking lots.

Introduction

Parking is usually considered a significant contributor to the overall performance of the traffic network, especially in dense urban areas that are heavily car-oriented. Cruising for parking can adversely impact on traffic by increasing congestion and likelihood of incidents (Wang and He, 2011). It lengthens travel times, increases fuel consumption, and worsens the environmental effects of cars.

Previous research has shown that pre-trip information about parking can help customers reduce their parking search time, the corresponding fuel consumption and the likelihood of road accidents, while enhancing customers' overall parking experience (Bock et al., 2019; Kim et al., 2014; Rajabioun et al., 2013; Yang and Lam, 2019). Parking information systems (PIS) provide drivers with real-time information about parking availability and navigate them to a vacant space to assist them with their trip planning (Milosavljevic and Simicevic, 2019).

PIS are considered a crucial part of smart city management frameworks, specifically intelligent transport systems (ITS) (Yang and Lam, 2019; Yang et al., 2003). Given their role in provision of information to assist customers with their travel planning, PIS can be integrated into advanced traveler information systems (ATIS) (Shiue et al., 2010). ATIS, as the most comprehensive trip planning solutions, aim at providing road users with accurate and reliable real-time information about traffic, parking and available alternatives enabling them to make more informed decisions. ATIS in general, and PIS in particular, help improving the overall traffic flow, reducing congestion, incidents and environmental effects, and enhancing user experience (Li, 2019; Milosavljevic and Simicevic, 2019).

PIS at a Glance

One major objective of PIS is to provide drivers with real-time availability details, specifically to reduce cruising for parking (Teng et al., 2008; Yang and Lam, 2019). PIS may also include routing, fee collection and payment management, and availability forecasting features, in addition to the system's common information provision function (Hui-ling et al., 2003; Rajabioun et al., 2013; Yang et al., 2003). PIS may incorporate advanced algorithms for routing drivers to the most suitable parking space, considering each user's preferences and past parking behavior (Rajabioun et al., 2013). Furthermore, these systems can provide users with estimated cruising time, given real-time/forecasted parking availability (Chen et al., 2016), and add it to their total travel time. PIS may also provide customers with space reservation capability, where the infrastructure supports it (Wang and He, 2011).

The information provided by PIS is either static or dynamic, as summarized by Hui-ling et al. (2003), one of the early studies on PIS. Static information may include parking lot location, total capacity, fees, physical restrictions (such as height and length limits), and usage regulations (such as maximum length of stay). Dynamic information includes real-time space availability and future occupancy forecast.

PIS use historical data, real-time data or both (Chen et al., 2016). Parking was usually neglected by conventional traffic management systems; however, more attention is being paid to parking and its impact on traffic in recently developed traffic management systems. Traditionally, traffic management systems relied heavily on historic data and well-established models. These systems are now increasingly integrating real-time data for more accurate and effective traffic management by gaining access to data produced by advanced ITSs. The integration of real-time data on traffic and parking enhances evidence-based and timely decision-making, which is necessary for efficient and safer use of traffic networks (Milosavljevic and Simicevic, 2019).

PIS Deployment

Most PIS rely on a network of space occupancy sensors and/or cameras to determine parking availability and to function effectively (Chen and Chang, 2011; Wang and He, 2011). Data from sensors and cameras transferred through a dedicated network to a central system are consumed by PIS based on the system objectives (Chen et al., 2016; Hui-ling et al., 2003).

PIS are often utilized along with variable message signs (VMSs) and/or web interfaces to inform customers of parking availability (Kim et al., 2014; Sun et al., 2016; Teng et al., 2008). VMSs usually guide customers through "en-route parking search," while a web interface can assist customers with their "pretrip parking planning" (Teng et al., 2001, 2008). Emerging interfaces such as mobile apps and in-vehicle parking guidance systems can help customers with their search and planning at both stages, pretrip and en-route (Teng et al., 2008).

The main factors recommended by the literature to be considered before deployment of a parking information system include (Teng et al., 2008):

- difficulty of finding parking space as perceived by customers,
- customers' technology preference, and
- system costs.

Many PIS, relying on smart parking technologies, have been developed over the past decade. These systems, especially deployed for on-street parking, can play a crucial role in effective implementation of parking policies (Wang and He, 2011), such as reducing total vehicle mileages, increasing parking turnovers and encouraging use of off-street parking and more sustainable modes of transport. Table 1 lists examples of smart on-street parking trials and compares them in terms of their underlying technologies and overall performance.

System Architecture

A typical parking information system consists of four main elements, including detection (monitoring) mechanism, data collection and processing unit (control center), information dissemination (display) mechanism, and communication technologies (Kotb et al., 2017; Lee et al., 2016; Ni and Cao, 2017). The detection mechanism often includes a range of inter-related sensors and smart technologies used for monitoring parking utilization and controlling access-payments. The data collection and processing unit is responsible for aggregating all historic and real-time parking-related data obtained through the detection mechanism as well as other ITS technologies. This unit also processes the data, forecasts future occupancies and handles user requests such as reservations. The information dissemination mechanism is performed either through VMSs and/or web/smartphone interfaces. Finally, the communication technologies handle the transmission of data/information between the aforementioned system components. Figure 1 illustrates the abstract architecture of a common parking information system.

Table 1 Examples of smart parking trials

System	Years of operation	Technology	Reported accuracy	Notes
ParkNet	2010	Sonar	95%	Used Crowdsources data collectuin too-used less than one sensor per bay
ParkSense	2013	Mobile phones Wi-Fi	83%	Used beacons between mobile phones and Wi-Fi to infer parking status
Street parking System	2013	Magnetic	98%	
SFPark	2014	Magnetometer	86%	On and off-street solution-more than one sensor per bay
Smart Santander	2014	Ferromagnetic	Not Specified	Part of Smart City project
FASTPAK	Continuous	Magnetic	95%	includes a smartphone application
Geomii	Continuous	Magnetometer	86%	Provides real-time and forecasted parjubg availability
Integrated smart parking	Continuous	Radar	Not Specified	Traffic flow is sensed too -less than one sensor per bay required
Parking spotter	Continuous	Sonar/Radar	Not Specified	Uses crowdsourced data collection too -uses less than one sensor per bay
Smart parking	Continuous	Infrared and magnetic	Not Specified

Detection/Monitoring

Smart sensors and technologies are the key element in the architecture of PIS; they provide the system with the data required for effective planning and management of parking (Paidí et al., 2018). The detection mechanism, relying on sensors, may collect real-time data at a parking facility's entry/exit and/or at each single bay (Ni and Cao, 2017). The widespread use of smart sensing technologies, as the basis of the Internet of Things (IoT), may also support the detection/monitoring mechanism (Lee et al., 2016); sensors deployed for other ITS services may also be able to collect data on parking utilization.

Historical data or sample observations might also be used in lieu of, or in conjunction with, smart technologies collecting real-time data (Paidí et al., 2018). However, a lack of access to real-time and accurate data may adversely impact on the reliability and effectiveness of PIS.

Data Collection and Processing

Another important element of PIS is a data collection and processing unit, which includes a central data warehouse or data lake, where all parking data are aggregated. Other relevant data, such as traffic and weather conditions, might also be integrated with parking data to provide a more comprehensive basis for processes performed by PIS (Li, 2019). The aggregated, and potentially processed data, can efficiently be shared with other transport management systems and third-party applications (Dalangauskas et al., 2016), often through application programming interfaces (APIs).

The data collection and processing unit is also responsible for data analysis, forecasting, and handling user requests. When a parking information system navigates users to a specific parking place, this unit also handles optimal route generation and user navigation. Big data methods and cloud-based technologies are increasingly used by PIS to efficiently store and process large volumes of data (Fang et al., 2016).

Information Dissemination

Dissemination of information is usually handled through VMSs, web/smartphone apps or both. VMSs may be used in two different positions helping users with their en-route decision-making and navigation to the optimal parking bay (Ni and Cao, 2017): (1) on the road or at the entrance of parking facilities showing availabilities and other relevant information such as prices, and (2) along the path in a parking facility guiding users to best available alternatives. Web interfaces and smartphone applications, on the other hand, provide users with more detailed information about parking and help them with pretrip planning as well as en-route decision-making and navigation (Ni and Cao, 2017).

Communication Technologies

Finally, PIS rely on a range of wired and wireless communication technologies to relay real-time data from sensors and smart technologies to data warehouses and processing units. Such technologies are also needed to transmit system outputs and commands to parking management technologies and VMSs. Similar to smart sensors, these communication technologies might be part of a bigger ITS.

Requirements of PIS

As mentioned earlier, smart sensors and technologies which collect data on parking occupancy and utilization are essential for effective functioning of PIS. These sensors range from magnetometers to LPR, and vary widely in terms of their cost, accuracy and collected details. This is especially important, as the reliability and effectiveness of PIS depends on the accuracy and timeliness of the data collected by these sensors (Milosavljevic and Simicevic, 2019). Table 2 shows the range of sensors which are commonly used in conjunction with PIS.

Overall, these sensors and smart technologies are categorized into “on-roadway” and “off-roadway” (Kotb et al., 2017). On-roadway sensors, such as loop detectors, magnetic sensors, and radio frequency identification (RFID) sensors are installed on a road’s surface or embedded into it. Off-roadway sensors, such as ultrasonic sensors, cameras, and ceiling-mounted infrared (IR) sensors are installed above the roadway. Sensors might also be classified as active if they depend on an external power source for their operation, and passive, otherwise (Al-Turjman and Malekloo, 2019).

Most smart sensors and technologies are still expensive and might need regular maintenance. Therefore, cost of real-time data collection is an important consideration for deployment of PIS (Paidí et al., 2018). Widespread adoption of ITS and the growing application of the IoT can significantly reduce such cost, as smart sensors and technologies are simultaneously used by more than one system (Lee et al., 2016).

Another important requirement of PIS is wireless communication technologies which transmit real-time data from sensors to data warehouses used by the PIS (El-Seoud et al., 2016). Smartphone applications may be developed to facilitate customer interactions, such as reservation, payment and navigation (Al-Turjman and Malekloo, 2019). Finally, security and privacy should be taken into account in data collection, storage and sharing; secure, encrypted communication is a significant requirement of PIS which determines their adoption by users (Al-Turjman and Malekloo, 2019).

Categories of PIS

PIS are usually categorized depending on their main objectives, although these categories may not be mutually exclusive. A parking information system—in its simplest form—is often referred to as a car park occupancy information system (COINS), and provides parking operators and users with real-time information on parking availability (Al-Turjman and Malekloo, 2019). This category of PIS, acting as a decision support system, mainly serves customers while searching for the best available parking option by providing them with basic information (Paidí et al., 2018). Table 3 presents examples of commercial PIS, which provide customers with availability and location of parking through a web and/or smartphone app interface.

Parking guidance (and) information systems (PGIS) is another major category of PIS, which mainly focuses on navigating users to a predetermined (and potentially reserved) parking bay. PGISs are often used for off-street parking. Centralized assisted parking search (CAPS) is a special type of PGISs often used in garages, which dedicates a parking lot to each incoming vehicle and navigates them to the right place (Al-Turjman and Malekloo, 2019).

Table 2 Parking occupancy monitoring technologies

Reservation-based smart parking systems (RSPS) is another major category of PIS that enable users to book parking space in advance (*El-Seoud et al., 2016*). Such a parking information system often relies on historic trends and also accommodates forecasting of parking availability for a user's requested time, to guarantee the vacancy of the reserved space at the given time (*Ni and Cao, 2017*).

Automated parking, with vehicle lifts and robotized vehicle displacing technologies, also uses a customized category of PIS which manages the automatic dispatching of vehicles to/from a dedicated bay, in addition to common PIS features (*Al-Turjman and Malekloo, 2019*). These PIS incorporate advanced algorithms to optimize the use of space and maximize operation safety.

Common Features and Functions of PIS

Depending on the purposes of a parking information system and the main category into which it fits, different types of features and functions are offered by the system. **Figure 2** represents the common features of typical PIS, as well as the actors using such a system. These common features can be classified into administrative and operation-related. Administrative features, mostly used by parking operators, provide access to intelligent parking management technologies, payment and transactions data as well as system configuration and troubleshooting. Operation features, used by operators, customers and third parties (such as smartphone

Figure 2 PIS actors and use cases Source: Adapted from Lin et al. (2017)

applications), provide access to analyzed data, facilitate parking utilization and management, and enable automated, smart operations such as contactless entries/exits.

Figure 3 illustrates common features and flow of information in typical PIS. Along with providing real-time information on parking space availability, PIS may also guide users to the optimal parking bay (Yang et al., 2003). This can be done from users' origin, on the road, and/or inside parking facilities. Physical signs and guiding systems, often in the form of VMSs, are commonly used to communicate availability and locations of vacant parking both on-street and in off-street garages (Milosavljevic and Simicevic, 2019). Figure 4 illustrates common information that can be presented through a PIS-connected VMS.

Intelligent Algorithms, Booking and Customer Management

Intelligent algorithms are also being used in advanced PIS. These algorithms can optimize the choice of parking for users, considering their objectives and constraints, such as price, availability likelihood and distance to final destination (Dalangauskas et al., 2016). PIS may even collect personal preferences and use machine learning algorithms to develop user-specific profiles including their final destinations, regular parking patterns and payment choices. Table 4 summarizes potential factors which may be

Figure 3 Main features and flow of information in a typical parking information system. Source: Adapted from Li (2019)

Current date and time: 21 May 2020 15:45				
Parking	Total Spaces	Available Spaces	Occupancy	Trend
1	290	100	66%	↑↑
2	480	230	52%	⇒
3	100	20	80%	↓↓

Table 4 Summary of potential factors to consider for personalized parking choices

Category	Factor	Description
Parking constraints	Availability	Current availability of parking spots at each location
	Parking rules	Parking duration limits, bin collection, height and length limits
	Rates	Hourly (\$/hour), flat rates, free period
Driver preferences	Parking type	On-street, off-street, valet
	Time or expense	Driver's preference of paying less or reaching their final destination sooner
	Parking duration	Driver's preferred length of stay
Traffic condition	Arrival time	Driver's preferred time of arrival at final destination
	Driving time	Travel time from the current location to each parking alternative
	Walking distance	Walking distance between each parking alternative and final destination
	Total travel time	Sum of driving time and walking time

Source: Adapted from Rajabioun et al. (2013)

considered by PIS while generating and updating user profiles. These profiles are later used to determine the best customized alternative for each user (Rajabioun et al., 2013).

Booking is another feature offered by PIS, which is especially relevant for off-street parking (Yang and Lam, 2019). Accordingly, PIS may also incorporate billing and account management to automate customer management, handle payments and generate invoices. Furthermore, PIS also provide accounting and auditing features to effectively manage parking cashflows (International Parking Institute et al., 2018).

Another main feature of PIS is the ability to forecast the likelihood of parking availability (Bock et al., 2019; Liu et al., 2006). In addition to historic and real-time parking occupancy, a PIS may also integrate weather, traffic flow, road conditions, and special events to improve the accuracy of forecasts (Yang et al., 2003).

PIS often include data analytics features providing parking operators with summaries, models and insights on parking utilization (Liu et al., 2006). These features can be used to generate “actionable” information; the information about trends and system performance which facilitates incremental operation improvements and change implementations (International Parking Institute et al., 2018).

PIS often include features to differentiate potential usages and customers. In addition to time-dependent fee structures, parking regulations and fees might change due to special days and events. Furthermore, parking facilities usually serve different groups of customers with specific needs and preferences (e.g., valet users or mobility-impaired customers). PIS should allow easy specification and implementation of such differentiating structures (International Parking Institute et al., 2018).

PIS may also be capable of determining optimal parking price based on demand and operation objectives (International Parking Institute et al., 2018; Wang and He, 2011). Some PIS incorporate features to detect illegal parking and facilitate efficient enforcement (International Parking Institute et al., 2018; Sadhukhan, 2017).

Access Control, Automation, and Emerging Features

PIS can also be linked to parking gates, license plate recognition (LPR) systems, and other physical instruments, such as weight and height sensors used in automated car parks (Dalangauskas et al., 2016). Contactless payments of parking fees is possible only with the support of PIS (El-Seoud et al., 2016; Yang and Lam, 2019). Therefore, PIS often plays a central role in the automation and enhanced sustainability of modern parking facilities.

Several features and function are also being integrated into advanced PIS to address emerging needs and trends in ITS and sustainable parking management (Ni and Cao, 2017). An important feature is the capability of communicating with self-driving vehicles, specifically to guide them to a predetermined parking bays (Al-Turjman and Malekloo, 2019). Another emerging feature is providing and managing extra services at parking bays needed by advanced electric/hybrid vehicles, such as charging their batteries. Finally, scheduling the use of shared autonomous vehicles and dispatching them to customers is a potential feature needed in future PIS.

Benefits and Advantages of PIS

Hassoune et al. (2016) provides a summary of advantages and disadvantages of multiple smart parking systems, given their underlying technologies and main PIS features. Overall, PIS enable more efficient use of parking space, reduces cruising for parking, and enhances user experience (Milosavljevic and Simicevic, 2019; Roman et al., 2018). This is especially relevant in situations where parking capacity is used unevenly across time and space. The unbalanced parking utilization is often due to incomplete information about alternatives and real-time/future availability. Balanced parking utilization optimizes the usage of existing capacity and reduces the overall cost of searching for parking for all customers (Chai et al., 2019).

Improved Traffic Efficiency

Previous research has shown that pretrip information about parking significantly impacts on users’ decision-making and results in more efficient use of parking and traffic network (Bock et al., 2019; El-Seoud et al., 2016; Tasserou, 2017). Providing such information, combined with navigation features, PIS can save customers’ time, while reducing their vehicle mileage and depreciation (Yang and Lam, 2019). Furthermore, pretrip knowledge about high level of occupancy and difficulty of finding parking close to a user’s destination may even motivate them to use a more sustainable mode of transport such as public transport or cycling instead of car (Milosavljevic and Simicevic, 2019).

Enhanced Customer Satisfaction

Availability of the reservation feature in a parking information system can also enhance user satisfaction, while enabling parking operators to increase their revenue and to optimize their capacity utilization (El-Seoud et al., 2016; Yang and Lam, 2019). Automated and contactless payment along with connected entry/exit controls also reduce congestion around parking facilities and improve user experience (Yang et al., 2003). PIS can also reduce cruising in off-street parking by navigating users to vacant parking, which in turn decrease congestion and vehicle emissions and likelihood of incidents (Dalangauskas et al., 2016).

More Effective Parking Management

Finally, effective PIS can result in lower illegal parking rates (Roman et al., 2018). PIS can also enhance car safety in off-street facilities through integrated safety and enhanced monitoring features (Hassoune et al., 2016).

Acknowledgment

This research is funded by iMOVE CRC (project 3-002) and supported by the Cooperative Research Centres program, an Australian Government initiative.

Biography

Dr. Behrang Assemi is an iMove postdoctoral research fellow at Queensland University of Technology, Australia, researching parking utilization, choice, and related congestion. He is a lead data scientist with 18 years of experience in both industry and academia. He has published papers in leading journals, for example, *Transportation Research Part A*, *Transportation Research Part C*, and *IEEE Transactions on Intelligent Transportation Systems*.

Dr. Douglas Baker is Professor in the School of Built Environment at the Queensland University of Technology, Brisbane, Australia. Dr. Baker's areas of expertise include land use planning, performance-based measurement, airport management, transit-oriented development, and regional governance. He has worked in the public and private sectors and conducts research in applied infrastructure and logistics solutions.

Introduction

The paradox of parking and future sustainability lies in how we have tied parking to the automobile, which has traditionally been used for commuting — causing pollution, greenhouses gases, and congestion on roads. As of 2018, there were more than 1.2 billion vehicles in the world (Wessel and Yoka, 2018), mostly comprised of private cars; these cars are parked on an average 95% of the time (Morris, 2016). Cruising for parking, especially in busy urban areas with limited parking availability, adversely impacts on traffic congestion and exacerbates the resulting air pollution (Lee et al., 2017). Parking, as a use of space, is associated with the use of single occupancy vehicles and the impacts created from their use. Large cities around the world are struggling to make a balance between the demands for more parking and the capacity to supply parking, while minimizing the abovementioned adverse consequences (Cavaldón, 2014).

Parking is a critical transport resource in urban centers that services a wide range of clients and uses. Wessel and Yoka (2018) suggest that the relationship between parking and sustainability lies in parking as a land use, building type, and form of transportation. We argue that parking needs to be conceptualized as a link between mobility and transport, and that space for parking is changing in its role as a destination in urban centers.

Therefore, the management challenge becomes changing parking from a prescriptive land use, where land uses are prescribed by zoning, to a link in mobility that is controlled by performance-based standards. Traditionally, in most cities and councils, parking utilization is controlled by the zone in which it resides; thus, the priority use that determines parking is the type of zone. For example, in a residential zone, on-street parking is regulated for local residents and guests. This may vary from all-day parking to prescribed time limits (time of day, length of stay, permit, or meter) depending on the demand and surrounding density. In a commercial zone, parking is often allocated for short-term customer access. The point is that in prescriptive zoning there are multiple management strategies for on- and off-street parking designed for a specific land use type. However, as Elliott (2012, p. 2) notes, “. . . many current zoning systems adjust poorly to changed circumstances; and reflect and encourage poor systems of city governance.” A performance-based approach can address such shortcomings (Baker et al., 2006; Frew et al., 2016).

How should parking then be managed as a link in the transport chain, or be conceptualized as part of an individual's mobility? The argument forwarded here is that parking is a destination point and part of a mode sequence, where performance standards can be adapted to suit the required modes of transport. Furthermore, such standards can be defined in a way to support sustainable urban development (Cavaldón, 2014). However, a different approach is required to manage parking space that does not tie parking to stringent, nonflexible zoning standards. Currently, there is no coherent framework for measuring parking performance considering its role in the transport mode sequence. Moreover, little is known about how to implement parking performance standards as a management tool due to both a lack of empirical data and an overarching theoretical framework.

Accordingly, the focus of this chapter is to introduce performance standards as a means to manage parking in a more efficient method and as a part of the transport journey. Research on performance-based planning has not integrated parking as a land use, yet parking is one of the dominant land uses in the urban core. The main challenge is how we define and enforce the performance indicators used for parking. As the first stepping stone, we build on the current literature to propose a conceptual framework for performance-based parking management in this study. In this framework, we incorporate well-known, mostly economic measures of parking performance. This framework quantifies the performance of parking spaces, and thus it enables planners and parking operators to consider relevant measures and achieve management objectives. Such a framework can play a crucial role in developing

Fig. 1 Performance-based versus prescriptive planning.

actionable strategies for achieving long-term sustainability goals, especially as the majority of human beings will be urban dwellers by 2100 (West, 2017).

The remainder of this chapter is organized as follows. Section Literature Review reviews the literature on performance-based planning and parking performance measurement. Section A Framework for Performance-Based Parking Management presents the proposed the performance-based framework for parking management. Finally, Section Conclusion concludes this study.

Literature Review

Performance-Based Planning

Performance-based planning is increasingly applied to the public sector as a means to improve the efficiency and effectiveness of decision-making (Frew et al., 2016). Performance-based planning is built upon the assumption that the impact of land use is a function of intensity rather than specific use. Thus, performance-based approaches set standards that describe the desired end results and acceptable limits of impacts (Aigwi et al., 2019). This type of planning is supposed to be more flexible, require fewer regulations, speed up the approval process, and encourage a greater dialogue among stakeholders, as opposed to traditional prescriptive planning (Blumenauer, 2011). Fig. 1 provides an abstract representation of these two types of planning to highlight their main differences.

However, there are considerable challenges in applying performance-based planning to regulatory contexts (see Baker et al., 2006; Frew et al., 2016). According to Blumenauer (2011), there are five major considerations when developing and implementing a performance-based approach:

1. solutions should be comprehensive;
2. accountable partnerships should be formed;
3. explicit, precise outcomes should be defined and the corresponding performance indicators should be developed;
4. accountability should be encouraged to ensure the integrity of the process and the likelihood of achieving the outcomes; and
5. participation should be voluntary.

A successful implementation of performance-based planning is dependent on the application of indicators to measure performance standards (Vullo et al., 2018). More specifically, the desired outcomes within the plan are contingent on applying indicators at various levels to evaluate impacts and regulate activities. Indicators are used in a performance-based planning framework as a means to monitor baseline conditions to ensure that regulatory standards are being met. As a result, these indicators can be used to evaluate the relative success of the planning process against the predetermined planning objectives. In addition, the strategic and normative directions of the plan can constantly be measured using an indicator approach. Indicators can be vertically integrated to measure the planning process at different performance levels.

The application of indicators to land use planning is a complex and conceptually difficult problem. The primary difficulty arises from the evaluation of the planning process. What do we evaluate and how do we do it? Almost two decades ago, Briassoulis (2001) wrote on the complexity of measuring sustainable development in planning by using indicators: indicators are “a long way from making a substantial contribution to planning” due to their lack of integration, fragmented assessment of sustainable development,

and poor theoretical assumptions in the application of indicators; the dimensions of the problem incorporate basic questions such as “what do we measure?”, “how do we evaluate what we have measured?”, and “is it relevant to where we need to go?”. These are tough conceptual questions that relate to the evaluation of the performance of planning and are not easily answered. This continues to be the case today, although changing technology is allowing a broader application of indicators in planning and regulation.

Part of the answer to these questions about indicators lies in the definition of a model of planning and the application of an indicator framework to evaluate the planning process. The correlation of indicators to what they measure is essential. Indicators are a means of performance evaluation. They define: (1) what to measure; (2) how to measure; and (3) how to communicate measurement results.

Most often, indicators provide a method to measure output, efficiency, outcome, and/or productivity. An indicator “is something that points to an issue or condition” and “helps you understand where you are, which way you are going, and how far you are from where you want to be” (Hart, 1999, p. 26). Piasecki et al. (1999) suggest the purpose of any performance measurement in business is to change behavior. Thus, the main functions of indicators are to provide (1) an assessment of conditions or trends, (2) a comparison across places or situations, (3) an assessment in relation to goals or targets, (4) early warning information, and (5) an anticipation of future conditions or trends (Gallopín, 1997).

The literature on the use of indicators is extensive and spans a wide range of topics. Despite the differences in the application of indicators, there are criteria that are internal to the use of indicators common to all fields (see Alberti, 1996; Bossel, 1999; Gallopín, 1997; Hart, 1999; Milosavljevic and Simicevic, 2019). Generically, indicators should:

1. be appropriate to the context and reflect the system properties;
2. be easy to interpret and understand;
3. be analytically sound, incorporating reliability, and validity;
4. have a timeliness in order to respond;
5. be compatible within the system; and
6. be comparable outside the system.

Each of these characteristics defines a necessary criterion for the successful application of indicators as a means to measure performance and inform decision-making.

Finally, it is worth highlighting that there are two types of indicators. The first type consists of indicators used for measurement; these indicators set compliance levels or conformance to industry standards. This type of indicators is empirical and includes measurement in decibels, parts per million, pH levels, and other standards required by legislation or internal company standards. The second type of indicators measure the effectiveness of performance. Indicators of this nature evaluate internal programs, desired outcomes, productivity, and performance (Jasch, 2000). These indicators evaluate internal outputs such as “how are we doing inside the system?” and “are we achieving what we set out to achieve?”, as well as external outputs such as “how do we compare with similar entities?”. Both types of indicators have to be applied congruently in order to measure performance.

Parking Performance

Traditionally, the performance of parking has been measured and evaluated using localized survey-based indicators. Furthermore, given that mostly ad-hoc and uncoordinated procedures are used for parking management, parking use has usually been inefficient in many large cities (Willson, 2018). However, by introducing the Internet of Things (IoT) and innovative data collection and analytics technologies, a variety of tools and methods (sensors, pricing mechanisms, and real-time information systems) are becoming widely accessible, which enable more effective and accurate measurement and management of parking performance (Al-Turjman and Malekloo, 2019; Willson, 2018).

Within the context of parking planning and management, performance indicators can be defined and implemented to enable and facilitate achieving sustainable outcomes (Milosavljevic and Simicevic, 2019). This is especially relevant, as the most recent parking management practices consider parking as a service rather than an object, and thus the ultimate goal of such practices is to maximize parking service efficiency given both its financial and environmental aspects (Shoup, 2018).

As highlighted in the earlier section, careful development and effective implementation of performance indicators play a crucial role in the success of a performance-based planning framework for parking. Such indicators should enable a simple evaluation of compliance/conformance of parking with a predetermined financial standard, while providing the opportunity of assessing the effectiveness of parking performance toward higher sustainability (Milosavljevic and Simicevic, 2019). Parking performance, however, has often been evaluated through simple financial measures (Willson, 2018), such as the parking space occupancy over 24 hours, addressing the financial objective alone. It is important to define and implement parking sustainability indicators in order to develop an integrated framework for sustainable performance-based parking planning (Yoka, 2014). For example, the total number of parking spaces in the CBD of Portland, US, has been capped since the 1970s as a means to decrease private vehicle usage specifically to comply with an air quality maintenance plan focusing on carbon monoxide and ozone emissions (Blumenauer, 2011).

Every element of parking practice, from planning and designing the parking structures to searching for and booking a parking place, plays a crucial role in realizing potential management goals (Leinart, 2015). Air pollution is the most obvious impact of parking on the environment, caused by the emissions of vehicles traveling to parking facilities and cruising to find parking

Table 1 Parking performance measures

<i>Parking aspect</i>	<i>Measure</i>	<i>Description</i>
Land use	Land use cost-effectiveness	Level of efficiency in using the land dedicated to parking considering other potential uses of the land
	Turnover / Index	Turnover is the total number of vehicles parked in a parking bay during a given period of time Index is the percentage of time where a given parking bay is occupied
	Average duration	Average duration of parking utilization for all vehicles parked in a parking facility
	Land use mix	How mixed and/or multi-modal is the land
	Shared use	The extent to which the parking is shared for multiple uses (e.g., residential, office and entertainment)
Building	Land use effectiveness	How well the land is preserved, it provides community spaces and it promotes sustainable urban living
	Capacity	Efficiency in parking supply given the total available space
	Building cost-effectiveness	Cost-effectiveness of the parking considering its construction and operational costs as well as its revenue
	Overflow plan efficiency	Efficiency of overflow management plans for occasional extra parking demands
	Spill-over level	Average spill-over over 24 hours
Transportation	Availability	Space availability likelihood
	Walkability index	Range of destinations which can be serviced by the parking facility through walking
	Mobility index	Extent to which the parking facility enables mode change as a mobility hub
	Usage diversity index	Diversity of user types and/or destinations served by the parking
	Value usage ratio	Share of space dedicated to higher-value uses (e.g., service vehicles, deliveries, and people with special needs)
	Enforcement efficiency	The extent to which parking regulation enforcement is “efficient,” “considerate,” and “fair”
	Shared economy index	The extent to which the parking facility enables shared mobility services
	Alternative modes index	The extent to which alternative, more sustainable modes of transportation are supported

(Čuljković, 2018; Wessel and Yoka, 2018). Other environmental effects of parking include energy use, such as for lighting, although this is often not significant (Wessel and Yoka, 2018). Cruising for parking has also significant negative economic consequences, accounting for 8%–74% of total traffic in some areas and averaging between 3.5 and 14 minutes in each occasion (Lee et al., 2017).

Parking as a mobility service relies on a balanced combination of solutions and practices which address economic, public health, and environmental sustainability. The ultimate goal of such solutions and practices is to minimize fossil fuel use, vehicle emissions, and unsustainable land use (Geneletti et al., 2017; International Parking Institute, 2017).

Wessel and Yoka (2018) argue that the relationship between parking and sustainability can be investigated considering parking as a “land use,” “building type,” and “transportation” hub. From the land use perspective, valuable, sometimes very scarce, land resources are used to build parking facilities, whereas these resources could be used for a wide range of other purposes (Wessel and Yoka, 2018). Furthermore, the use of advanced materials and technologies in parking structures can significantly reduce the energy consumption in parking, while simultaneously enabling more efficient methods of finding parking with less driving (Yoka, 2014). Finally, Leinart (2015) argues that parking must be considered as a fully integrated element of the transportation system, which encourages active and sustainable modes of transport instead of single-occupancy vehicles (SOVs). This view or approach can lead to higher sustainability goals.

A Framework for Performance-Based Parking Management

Table 1 provides an overview of a proposed performance-based framework for sustainable parking management. As outlined in Table 1, we propose performance measures across the three major aspects of parking as: (1) a land use, (2) a building, and (3) an element of transportation (Wessel and Yoka, 2018). We have included common financial parking performance measures in the framework as defined and used in the literature (e.g., Litman, 2006; Milosavljevic and Simicevic, 2019; Shoup, 2011). The framework also includes sustainability performance measures across the three aspects of parking proposed in this study, and thus it is a multi-criteria performance-based framework (Vullo et al., 2018). The next subsections elaborate on the proposed framework and its performance measures.

Land Use Performance Indicators

We recommend land use cost-effectiveness as the main land use performance indicator of parking from a financial perspective. This indicator concerns how efficiently the land dedicated to parking is being used, considering all other potential uses of the land. The land dedicated either to on-street or off-street parking in dense urban areas is scarce and a valuable public resource in most cities. Thus, it is important to measure how cost-effective is to use it for parking rather than any other alternative (Willson, 2018).

Fig. 2 Moray street bike path design as a part of the Victoria's government "Metro Tunnel" project (image courtesy of the State Government of Victoria, 2018).

The literature has also used parking turnover and/or parking index as other indicator(s) of the efficiency of parking space utilization (K. Al-Obaidi et al., 2018; Milosavljevic and Simicevic, 2019). Parking turnover considers the use of both space and time; it is the total number of vehicles parked in a parking bay during a given period of time. Thus, the higher turnover indicates a better land use performance, because a larger number of customers have used the parking during a specific period.

The parking index, on the other hand, is the percentage of time where a given parking bay is occupied (K. Al-Obaidi et al., 2018; Mathew, 2014). While it also indicates the extent to which the parking land is used by customers, it does not consider the shared utilization of the land by "different" customers. Therefore, it is a weaker indicator of efficient land use, compared to parking turnover.

Land use mix is a common indicator of a parking lot's performance from a management perspective. This indicator reflects the extent to which a parking facility is used for purposes other than its primary objective (parking). A higher land use mix often indicates multi-modal transit-oriented development of the parking facility, which integrates a balanced mixture of services and facilities to minimize the need for driving. A high land use mix can promote the idea of "park once and walk" to multiple destinations, enhance place making, and better integrate the community (Timothy Haahs and Associates, 2013). Shared use ratio is a similar indicator, which has been used in the literature; it indicates how much the parking space is shared for different uses, including residential, office, and entertainment (Timothy Haahs and Associates, 2013).

Finally, average parking duration, as the average duration of parking utilization for all vehicles parked in a parking facility, is another common indicator of land use performance (K. Al-Obaidi et al., 2018; Mathew, 2014). City planners often prefer shorter average parking duration for on-street and longer average parking duration for off-street parking facilities, supporting a higher shared utilization of often scarce on-street parking.

Land use effectiveness can be used as an indicator for the land dedicated to parking. However, this indicator can be expanded to other uses within the context of urban living (Timothy Haahs and Associates, 2013). The land used for parking need not be exclusive and can be integrated into other uses. Fig. 2 provides a cross-sectional example of parking land use, which effectively enhances the bike lanes' safety and thus promotes more sustainable modes of transport.

Building Performance Indicators

Building performance indicators are concerned with how efficient and effective a parking facility (either on-street or off-street) can be used. Parking capacity provides an indicator which corresponds to the total capacity of a parking facility. It becomes an effective performance measure if used as a relative indicator: the ratio of the actual capacity of a facility to the maximum potential capacity of the same facility if it was designed in a different way. Such relative indicators demonstrate the extent to which the parking space is wasted due to design and technological issues; while it could be used more effectively through a smarter design, more compact stalls and use of advanced car stackers.

Another indicator of building performance is its cost-effectiveness. This indicator reflects the trade-off between a parking facility's revenue and its construction and operation costs, regardless of being on-street or off-street. It shows how well the parking costs are managed through the use of advanced building material and parking operation technologies (for example, solar-powered lighting, and access control). It is also indicative of how well the corresponding parking price strategies work in practice.

Overflow plan efficiency is a building performance indicator, relevant for off-street parking facilities only. This indicator reflects how the overflow management plan and its supporting practical elements (real-time guidance information, signs, and paths)

perform in efficiently handling occasional extra-parking demands. An efficient overflow plan results in smoother traffic in and around the parking facility, enhances the customer experience, and impedes potential negative effects of mismanaged overflow traffic on other users of the surrounding area. Parking spill-over, measured as the average spill-over during a specific period of time, is a similar indicator used in the literature.

Transportation Performance Indicators

As a key element in the transport system, parking performance has often been examined through a wide range of transportation performance indicators. A parking availability index is an example of an indicator which corresponds to the probability of finding a parking space in a specific area at a specific time (Milosavljevic and Simicevic, 2019). Parking search/cruise time is a similar measure used in the literature (e.g., Milosavljevic and Simicevic, 2019), indicating the average time spent by drivers to find an available parking space in a specific area at a specific time. Accordingly, this indicator also reflects parking availability and demand; however, it is also affected by overall status of the transportation system other than parking (traffic flow) in a particular situation of interest.

The walkability index is another transportation performance indicator of a parking facility, reflecting the extent of destinations that are easily accessible by walking from the parking facility. It plays a central role in the emerging trend of park once and walk facilities, which help reducing motorized trips (Timothy Haahs and Associates, 2013). The average/shortest walking distance/time from a parking facility to a user's final destination is a similar performance indicator used in the literature (Milosavljevic and Simicevic, 2019).

A mobility index indicates how well a parking facility acts as a mobility hub by enabling mode change for its users. A parking facility with a high mobility index often provides easy access to bike-sharing facilities and/or bicycle storage areas. Furthermore, such parking also facilitates the use of public transit to multiple destinations, and thus it encourages more efficient and sustainable travel patterns. Therefore, parking with a higher walkability and/or mobility index promotes environmentally friendly transportation, reduces private car usage and congestion, and improves air quality.

The usage diversity index is similar to the mobility index; however, it is mainly concerned about the diversity of a parking facility's users as well as their destinations (Milosavljevic and Simicevic, 2019). The value usage ratio reflects the share of space dedicated to higher value usage (e.g., service vehicles, deliveries, and people with special needs). Therefore, it is an important performance indicator of parking as a common, shared resource, and identifies how well the whole community is served by the facility (rather than just private car owners).

Enforcement efficiency is an indicator of parking performance demonstrating how successful the enforcement policies and practices are in realizing the predetermined objectives of a particular parking planning scheme from the transportation perspective (Milosavljevic and Simicevic, 2019). This indicator is also concerned about parking users' perceptions of fairness in policy implementation.

A shared economy index is another indicator of a parking's environmental transportation performance that reflects the extent to which the parking facility enables shared mobility services. This includes the availability of car- and bike-sharing vehicles in the facility. Similarly, an alternative modes index determines the extent to which more sustainable modes of transportation are supported by a parking facility. This includes, but is not limited to, the availability of electric vehicle charging stations and electric scooter/bicycle docks (Timothy Haahs and Associates, 2013).

Conclusion

Performance-based management offers a different view of urban space dedicated to parking and provides a more flexible approach to parking. The benefit of this method for management is to consider parking as a service rather than an object, and thus one of the goals is to maximize parking service efficiency. In addition, by incorporating a wide range of indicators, a performance-based framework can integrate wider stakeholder engagement outside of parking specialists and private car users.

The primary advantage of a performance-based approach is that it is adaptable — with a wide range of financial and sustainability indicators. The indicators have the opportunity to be objective and service-oriented (for the client), and the focus is outcome-based. We argue that this offers a new direction in which to view land use for parking and to change the focus of space for cars to space for mobility opportunities. This framework also enhances cost efficiency for all stakeholders, including developers, parking lot owners and users. An indicator-based approach helps to adapt existing parking facilities to the needs of smarter, more sustainable cities (Michalec et al., 2019).

Overview

Transit priority, also known as the Transit Signal Priority (TSP), is a signal control strategy that grants priority to transit vehicles at signalized intersections. The purpose of transit priority is to assist transit vehicles in traveling through intersections quickly. Transit vehicles are given priorities by assigning green time to them so that they may travel through the intersection with a lower delay compared with vehicles of other movements (Lin et al., 2015).

Transit priority is a long-standing research topic that has been evolving for over half a century. The first transit priority was conducted in Los Angeles, California, in the United States in 1967 (Elias, 1974). The reason for introducing the transit priority was to maintain the competitiveness of transit service, which is mostly needed in populous urban areas (Baker et al., 2004). If the travel time of transit is short and stable, more residents will travel by transit instead of driving. This shift in travel mode helps to mitigate urban road congestion.

Transit priority improves the efficiency and reliability of transit service. By providing priorities to transit vehicles at intersections, transit priority helps transit vehicles reduce their waiting time. Therefore, they have shorter travel time along the route. If the transit priority is not provided, congestion at intersections may hold transit vehicles at intersections, preventing them from following the schedule by increasing travel time between stops and thereforereducing the punctuality of transit service. However, if the transit priority is granted, transit vehicles may not experience unpredicted intersection congestions, thereby improving punctuality and make transit service more reliable to passengers (Baker et al., 2004).

However, granting priority to a particular movement (i.e., through, left-turn, right-turn, U-turn, etc.) at intersections may adversely impact the efficiency of the nonprioritized traffic (Balke et al., 2000; Lin et al., 2015; Ma et al., 2010). Therefore, transit priority should only be granted when it is necessary and beneficial. As sensor and communication technologies evolve, transit priority strategies are becoming more responsive to real-time transit demand and more flexible in providing priority in order to obtain a better balance between transit and non-prioritized traffic. These strategies can be classified into the following three categories (Baker et al., 2004).

- *Passive transit priority*: Passive transit priority only optimizes signal timing of intersections based on given transit information and generates a static signal control plan. Most research on passive transit priority were conducted from 1967 to the early 1990s.
- *Active transit priority*: Active transit priority entails detecting transit vehicles' travel demand and granting priority to these vehicles using one or a combination of basic strategies. This category of transit priority strategies was extensively researched from 1967 to the early 1990s.
- *Real-time transit priority*: Real-time transit priority optimizes signal timing of intersections for a specific performance index based on real-time information of both transit and nonprioritized vehicles. Research on real-time transit priority began in the early 1990s, partly replacing active transit priority.

The aim of this article is to present the basic concept of transit priority and analyse its strategies. The details of each category of transit priority strategies are outlined in separate sections. Then, the article addresses the handling of multiple priority requests, the signal coordination for transit, and the combination of transit priority with other facilities in the following sections. A summary and future directions for transit priority are provided in the last section.

Passive Transit Priority

Passive transit priority strategy optimizes signal timing of intersections based on given transit information in an off-line mode and generates a static signal control plan. This priority strategy does not require the detection of approaching transit vehicles (Skabardonis, 2000). All transit-related information, including the distribution of bus arrival time and dwelling time at bus stops, is input for optimization.

There are several approaches to modify the original signal control plan in order to achieve transit priority (Baker et al., 2004; Skabardonis, 2000). The first approach is to adjust cycle lengths and signal timings. Reducing cycle length may reduce the waiting time of transit vehicles at red signals and therefore reduce transit delays. As cycle length changes, the length of each phase should change accordingly. However, reducing the cycle length may negatively impact the overall capacity and vehicle delay at the intersection. On the other hand, reducing the number of phases may reduce delay for all traffic at the intersection, including transit vehicles, since it saves total lost time.

The second approach is to split the phases. By splitting and repeating the phase corresponding to the prioritized movement, transit vehicles with different arrival times may encounter shorter red times and experience lower delays. However, the frequent phase transitions may increase the total lost time and reduce the overall capacity of the intersection. In addition, the corresponding phase should not be over-split since pedestrians need a certain period of green time to cross the road safely.

Passive transit priority is suitable for intersections with high and stable transit demand. Take the Bus Rapid Transit (BRT) system in Guangzhou, China as an example (Deng and Nelson, 2011; Wirasinghe et al., 2013). This is a busy system with over 30 transit routes operating on the same road. The travel speed of transit vehicles in Guangzhou BRT has been improved from 15 km/h to 21 km/h during peak hours due to dedicated lanes to transit vehicles, a reduced number of phases, and shortened cycle lengths at signalized intersections (Lin et al., 2015). In London, UK, passive transit priority provided better performance than other transit priority strategies when bus volume is higher than 60 vehicles per hour (Hounsell and Wu, 1996). However, a field test on Queen Street, Toronto, Canada in the 1990s showed no evident improvement in transit delay since transit volume was not stable (Yagar, 1993).

The advantages of passive transit priority are distinctive. Passive transit priority is simple and inexpensive to implement since it does not require sensors to detect transit vehicles. The signal control plan produced by off-line optimization is compatible with existing signal controllers (Hounsell et al., 1996; Ma et al., 2019; Skabardonis, 2000). However, passive transit priority does not consider the randomness of transit arrival time, making the system unable to respond to the time change of the transit arrive. Moreover, if no transit vehicle arrives during the prioritized phases, the passive transit priority would still unnecessarily give the green time to transit vehicles, which causes delays for nonprioritized traffic.

Active Transit Priority

Active transit priority detects transit vehicles' travel demands then grants priority to these vehicles using one or a combination of basic strategies. Travel demands are detected by sensors and sent to signal controllers, then signal controllers respond (Baker et al., 2004; Lin et al., 2015).

Compared with passive transit priority, active transit priority can respond to real-time transit demand. It considers the arrival time of transit vehicles at intersections and grants priority only when transit demand is present, which partly remedies one shortcoming of passive transit priority, namely, the granting of priority when priority is not needed.

Active transit priority needs some extra devices to obtain real-time transit information. The sensor for detecting transit vehicles could be a loop detector on a dedicated bus lane, a video camera combined with visual recognition techniques, Global Positioning System (GPS), or a Road Side Unit (RSU) that receives RFID or other radio signals from transits (Fan and Gurmu, 2015; Zhou et al., 2006). The signal controllers should be able to communicate with these sensors and respond to real-time information (Lin et al., 2015).

Active transit priority uses one or a combination of basic strategies to grant priority, including green extension, red truncation, and phase insertion. If the current phase corresponds to the transit vehicle's movement, the green extension strategy extends the green time of current phase when detects an approaching transit vehicle. In this way, the transit vehicle may travel through the intersection without encountering red light of the next phase. If the current phase does not correspond to the transit vehicle's movement but the following phase is for transit vehicles, red truncation terminates the red light of current phase in advance and provides green time to approaching transit vehicle so that the vehicle may experience less or no waiting time at the intersection. The phase insertion strategy inserts a dedicated phase when an approaching transit vehicle is detected (Lin et al., 2015).

To reduce the adverse impact of active transit priority on nonprioritized traffic, some strategies are proposed (Lin et al., 2015). Green compensation strategy provides extra green time to nonprioritized traffic after the transit vehicle left the intersection. However, there is still an extra delay for nonprioritized traffic during the compensation cycle (Lin et al., 2015). Another strategy restricts transit priority under some conditions. The British Department for Transport recommended a rule: only allowing red truncation, if there was no red truncation in the last cycle. The purpose of this rule is to prevent transit priority strategies from interrupting nonprioritized traffic too frequently (Department of Transport, 1977). The framework of active transit priority is summarized in Fig. 1.

Figure 1 Framework of active transit priority.

Active transit priority strategies can be further classified into two categories, namely unconditional strategies and conditional strategies (Lin et al., 2015). Unconditional strategies grant priority to every approaching transit vehicle, but conditional strategies consider schedule adherence of each transit vehicle. For conditional strategies, if the approaching transit vehicle is behind schedule, priority shall be granted to help the vehicle to catch up. However, transit vehicles on schedule or ahead of schedule do not receive priority (Hu et al., 2015; Skabardonis, 2000). Meanwhile, conditional strategies may introduce additional rules that prevent basic strategies from disrupting arterial or network signal coordination.

Active transit priority is suitable for a lower volume of transit traffic compared with passive transit priority. Unconditional active transit priority is more compatible with isolated signalized intersections since extending, truncating, or inserting phases may disrupt coordinated signal control. However, conditional strategies may mitigate this problem by adding coordination constraints to control rules. Moreover, active transit priority can handle high fluctuation in dwelling time and arrival time at intersections (Lin et al., 2015).

Active transit priority is a more sophisticated transit priority strategy compared with passive transit priority. It shortens the delay of nonprioritized traffic because it only grants priority on real-time transit demand. Active transit priority may also involve compensation and restrictive strategies that prevent delay of non-prioritized traffic from radically increasing. However, the basic strategies employed by active transit priority may severely impact the nonprioritized traffic and possibly disrupt the arterial signal coordination.

Real-Time Transit Priority

Real-time transit priority is a model-based strategy that optimizes signal control for a specific performance index based on real-time information of transit and nonprioritized vehicles (Skabardonis, 2000). The frequently used performance indexes are average transit vehicle delay, nonprioritized traffic delay, and average person delay (Ma et al., 2014, 2013). This approach requires the integration of transit priority and signal optimization so that the signal control plan would respond to the traffic demands (Lin et al., 2015). Real-time transit priority may consider factors from both transit and nonprioritized traffic, seeking a better balance between them.

Real-time transit priority requires more advanced sensors and communication technologies than the previously mentioned strategies. It could utilize Automatic Vehicle Location (AVL) systems (Hounsell et al., 2000) equipped on transit vehicles or Connected Vehicle (CV) technologies (Hu et al., 2015, 2014; Miucic, 2019) to obtain precise real-time information on transit vehicle locations and speeds, facilitating the prediction of arrival time at intersections. Furthermore, real-time transit priority may obtain the number of onboard passengers on each transit vehicle to support the optimization that uses person delay as the objective (Ma et al., 2014). Information from sensors on General Purpose (GP) lanes could also be considered, depending on the objective of real-time transit priority.

If data on the state of non-prioritized traffic is not available, minimizing total bus delay or average bus delay is a reasonable objective to improve transit efficiency (Head et al., 2006). However, if there are enough sensors to provide reliable and real-time information on nonprioritized traffic, considering the increase of nonprioritized traffic delay when transit priority is granted would be more comprehensive. Furthermore, if passenger count information on transit and non-transit vehicles are available, the impact of transit priority on passenger delay of nonprioritized traffic could be used as the optimization objective (Hu et al., 2014; Ma et al., 2014). This impact is two-fold, depending on the movement of non-transit traffic at the intersection. The person delay of non-transit traffic travelling in prioritized movements decreases, but the person delay of non-transit traffic of non-prioritized movement

increases. On the other hand, a multi-objective optimization model is also possible, which transit passenger delay, nonprioritized traffic delay, and transit schedule adherence delay in a comprehensive manner (Chang et al., 1996; Ma et al., 2013). Overall, if enough information is available, real-time transit priority should aim at reducing transit passenger delay without disproportionately increasing passenger delay of non-prioritized traffic. The optimization objective should reflect the overall benefit to the performance of the intersection, covering both transit and non-transit traffic.

The advantages of real-time transit priority are evident. It covers as many factors as possible, including the current states of transit and nonprioritized traffic. It may further optimize priority at the passenger level, producing the most precise results of balancing transit and nonprioritized traffic performance. Additionally, the variety of optimization models ensures flexibility in determining how to grant transit priority. However, in order to provide the information needed for optimization, the investments in infrastructure will increase (Lin et al., 2015). The cost-effectiveness of the real-time transit priority strategies should be thoroughly investigated before implementation.

Multiple Priority Requests

When transit traffic volumes increase and transit routes overlap each other, an intersection may need to simultaneously handle multiple priority requests from different approaches and different movements at the same time. There may be conflicts between these requests. For example, transit priority strategy cannot grant priority to two transit vehicles at the same time if their movements at the intersection conflict with each other. Therefore, it is vital to accommodate multiple priority requests while developing transit priority strategy, especially for active transit priority and real-time priority, which grant priority on real-time transit demand (He et al., 2014; Head et al., 2006; Lin et al., 2015; Ma and Bai, 2007).

Priority requests sent to an intersection could be arranged into a request queue in the order of received time, and it is the task of transit priority strategy to determine determining the order in which to respond to the requests in the queue and which requests to ignore. Two methods to handle the queue of multiple priority requests are the first-come-first-served (FCFS) policy and trade-off the overall performance of transit and nonprioritized traffic delay (Lin et al., 2015). The FCFS policy is an intuitive way, which is convenient to include in rule-based active transit priority. However, multiple studies have proven that the FCFS policy may not yield the best performance. Furthermore, FCFS ignores the schedule adherence of each transit vehicle (Head et al., 2006; Lin et al., 2015).

The second method, that is, trade-off strategy, may solve these problems. The order in which priority requests are served is determined by the model-based real-time transit priority, which optimizes the sequence by trading-off the performance of both transit and nonprioritized traffic. Performance indexes could be person delay and schedule adherence of transit vehicles. Multiple models, including decision trees (Ma and Bai, 2007), operations research models (Head et al., 2006), and mixed-integer linear program (MILP) (He et al., 2014), have been investigated for handling multiple priority requests, and the results have confirmed the advantage of real-time transit priority in accommodating multiple priority requests.

Signal Coordination for Transit

Implementation of transit priority at isolated intersections is not enough to reduce the overall transit vehicle travel time along the transit route. The travel time saved at one prioritized intersection might be neutralized by the downstream intersection if the two intersections are not coordinated for transit vehicles (Hu et al., 2015; Skabardonis, 2000). Therefore, transit priority strategies at intersections along the transit route should be coordinated to achieve systematic efficiency improvement for transit service.

All of the three categories of transit priority strategies can coordinate signal control plans for transit vehicles. For passive transit priority, signal coordination for transit may be achieved by either manually modifying the original signal control plan based on the transit headway setting (i.e., the interval of time between two neighboring transit vehicles moving in the same direction on the same route) of the transit schedule or including transit priority into the coordination optimization process (Lin et al., 2015). For the latter approach, take the off-line signal timing optimization software TRAFFIC NETWORK STUDY TOOL-7F (TRANSYT-7F) as an example. This software optimizes signal control plans for arterials and networks. Transit movements are modelled as separate links and assigned greater weighing factors for delay and stops. Then, these factors are included in the objective of the optimization (Skabardonis, 2000). Similar to single intersection strategies, passive transit priority performs better when transit traffic volume is high and stable when signals are coordinated (Lin et al., 2015).

For active transit priority, the control rules should be carefully designed to avoid oversaturated non-prioritized movements or disruptions to signal coordination (Lin et al., 2015; Skabardonis, 2000). Schedule adherence could also be used as the constraints for granting priority similar to in the single intersection scenario (Hu et al., 2015, 2014). The logic of active transit priority has been integrated with online signal control systems such as the Sydney Coordinated Adaptive Traffic System (SCATS) and the Split Cycle Offset Optimization Routine (SCOOT) (Ma et al., 2013). A field test of transit priority with SCOOT in London, UK, in 1999 demonstrated that transit vehicle delay could be reduced by 5–10 seconds per intersection without evident adverse impacts on nonprioritized traffic (Hounsell et al., 2000).

Real-time transit achieves better performance for both transit and non-prioritized traffic with the aid of advanced technology such as AVL and CV technology. First, the group of intersections to be coordinated should be determined. One can group all intersections on an arterial together within a pre-set distance or travel time threshold (Hu et al., 2015, 2014), or all intersections

Figure 2 An illustration of QJL.

Figure 3 An illustration of IBL on urban road segment.

between two transit stops could be grouped together (Ma et al., 2013). Then, the planners use the optimization model to determine the signal control plan of all intersections within the group based on transit priority requests. The objective could be the minimization both transit delay and nonprioritized traffic delay increased due to transit priority. The model should be able to predict the arrival time of each transit vehicle at all intersections (Lin et al., 2015). Both analytical evaluation and simulation results showed that signal coordination under real-time transit strategy could improve transit efficiency and schedule adherence at a low cost of nonprioritized traffic efficiency.

Transit Priority Combined With Other Facilities

Transit priority could be combined with other facilities that give transit priority on urban roads to enhance the effect of transit priority (Truong et al., 2017). Four types of facilities investigated in this section are Dedicated Bus Lane (DBL), Queue Jump Lane (QJL), Intermittent Bus Lane (IBL), and Bus Lane with Intermittent Priority (BLIP).

A DBL is the most common facility that gives transit vehicle priority on the road segments. Since there are no disturbances from non-prioritized traffic, the speed of transit vehicles is stable, and therefore, transit arrival time estimation at each intersection becomes more precise, which further improves the accuracy of optimization (Deng and Nelson, 2011). DBLs have been adopted by many BRT systems. A major shortcoming of DBL is that it reduces the capacity for non-prioritized traffic on the road segments (Viegas and Lu, 2004, 2001). In addition, the spatial-temporal resource may be wasted when the transit demand is low. Therefore, DBLs only suit urban roads with high transit volumes (Lin et al., 2015).

In order to assign spatial-temporal resources to both transit and non-prioritized traffic more accurately, unconventional facilities such as QJL, IBL, and BLIP have been proposed. The basic idea of QJL is to utilize a short stretch of lane, such as the right-turn pocket lane, so that transit vehicles may bypass the queue on the approach of the intersection (Farid et al., 2015; Zhou et al., 2006). An illustration of QJL is presented in Fig. 2.

In a QJL, the transit vehicle travels through the intersection. A right turn is allowed on the red signal; therefore, there will not be a queue in the right-turn lane. A special phase called the "jumper phase" is inserted when an approaching transit vehicle is detected. During the jumper phase, the non-prioritized through traffic that travels in the same movement as the transit vehicle is stopped, but a right turn is still allowed. The transit vehicle then uses the right-turn lane as a QJL to bypass the queue of non-prioritized vehicles. It merges back in front of the non-prioritized vehicle queue after it passes the stop line. Analytical and simulation results have demonstrated a significant decrease in transit delays for systems combining transit priority with QJLs (Farid et al., 2015; Zhou et al., 2006).

An IBL allows non-prioritized vehicles to use IBL when no transit vehicles present (Viegas and Lu, 2004, 2001; Viegas et al., 2007). An illustration of IBL is shown in Fig. 3. When a transit vehicle appears, non-prioritized vehicles downstream of the transit vehicle are not allowed to enter IBL by changing lane, but those already inside IBL may continue to use it. IBL signals are set up along the

Figure 4 An illustration of BLIP on urban road segment.

arterial to indicate whether non-prioritized vehicles are allowed to enter IBL, which are integrated with conventional signal controllers (Viegas and Lu, 2004). When a transit vehicle is detected, the signal controller at the local intersection controls IBL signals and intersection signals at the same time (Viegas and Lu, 2001). In this way, priority is granted both on the approach of the intersection and at the intersection itself.

An illustration of BLIP is shown in Fig. 4. Similar to IBL, BLIP also allows non-prioritized vehicles to use BLIP lane when no transit vehicles present. However, when a transit vehicle approaches, non-prioritized vehicles downstream of the transit vehicle and within a certain distance (i.e., the Clearance Range in Fig. 4) of that transit vehicle are instructed to vacate the BLIP lane, either by signals or by connected vehicle technologies (Carey et al., 2009; Eichler, 2005; Eichler and Daganzo, 2006). The BLIP is also open to non-prioritized vehicles upstream of the transit vehicle. This facility is suitable for transit routes with headway around 10 to 15 minutes or more. The popularization of connected vehicle technologies would enhance the effect of BLIP in reducing transit delays.

Summary and Other Issues

This article has reviewed three categories of transit priority strategies: passive transit priority, active transit priority, and real-time transit priority. The evolution of sensors and communication technologies has been supporting the development of more sophisticated transit priority strategies. Two crucial issues regarding transit priority are multiple priority requests at an intersection and signal coordination for transit. Systems can also combine transit priority with other facilities in order to achieve better performance. The advantages, shortcomings, and applicable conditions for the three categories of transit priority strategies are summarized in Table 1.

The core idea of transit priority is to reduce transit delay at the expense of the efficiency of non-prioritized traffic at the intersection. In order to grant the priority for transit and also to reduce the adverse impacts on other traffic, transit priority strategies try to balance the performance of transit and non-prioritized traffic. For transit, the frequently used performance indexes are transit delay or travel time stability along the transit route. For the non-prioritized traffic, frequently used indexes are delay reduction of non-prioritized traffic in prioritized movements, delay gain of non-prioritized traffic in non-prioritized movements, and capacity for

Table 1 Summary of three categories of transit priority strategies

Category	Characteristics	Applicable conditions
Passive transit priority	• Easy implementation • Low investment in infrastructure • Irresponsive to real-time transit demand	• High and stable transit volumes
Active transit priority	• Requires detection of transit vehicles • Grants priority on transit demand • Potential disruption to signal coordination • Transit vehicles in need of priority may be ignored due to restrictive strategies	• Lower transit volume with fluctuations • Fluctuations in dwelling time and arrival time at intersections
Real-time transit priority	• Requires advanced sensors and communication technologies • High investment in infrastructure • Supports optimizations on the passenger level • Considers the overall performance of the intersection • High flexibility	• Lower transit volume with fluctuations • Fluctuations in dwelling time and arrival time at intersections

non-prioritized traffic at intersections or road segments. Other performance indexes measure the overall impact of transit priority, such as the reduction in average person delay and the person capacity.

Future transit priority strategies may exploit emerging connected and automated vehicle (CAV) technology to enable more precise control of transit and non-prioritized vehicles. A cooperative bus priority system in the CV environment had been implemented and tested in Taicang, China. In addition to transit priority, the system instructed transit vehicles to drive at a suggested speed. The field test showed promising results in the reduction of transit delay, stops, and average fuel consumption (Wang et al., 2014). In CAV environment, transit vehicles are not only connected but also automated, which makes them respond to speed suggestions in a more precise way (Hu et al., 2015, 2014; Wang et al., 2014). Future transit priority strategies may consider interestingly controlling both signal and vehicle trajectories with the help of CAV technology in order to achieve better efficiency and environmental gain.

Furthermore, transit vehicles are simultaneously impacted by transit schedules and traffic signals. Current transit priority strategies more focus on traffic signal control. However, optimizing transit schedules together with transit signal priority may further improve the efficiency of transit without adversely impact non-prioritized traffic (Zhou et al., 2019). Future transit priority strategies may also consider the integrated optimization of transit schedules and signal control plans at intersections.

Introduction

Public transportation vehicles (e.g., buses), with the ability to carry a large number of passengers, can use limited road space more efficiently than private cars. Thus, increasing the share of passengers on buses can ultimately contribute to reducing traffic congestion and its associated externalities in urban areas. To this end, it is crucial for public transportation to offer high-quality services. This includes high reliability, competitive travel times, comfortable rides, dense network for high accessibility, competitive prices, unified payment system in the case of multiple operators, ease of transfers, etc. Some of these factors are very related to the design, while others are more specific to the operations of the system. In particular, service reliability, which has been shown to be a major predictor of public transportation ridership (Bates et al., 2001; Currie and Wallis, 2008), can be very much adjusted with operational strategies. Service reliability might refer to the guarantee that planned services are actually run, and that they adhere to the schedule. While the first aspect is an issue when there are budget cuts, broken vehicles, or other major disruptions to the system, the second aspect can be an issue on day-to-day operations, simply because of the normal fluctuations in traffic and demand. In this Chapter we focus on adaptive bus control as a means to increase the reliability of transportation systems for day-to-day operations. Such bus control can be implemented at the infrastructure level, during the dispatching process, or at the vehicle level (see Fig. 1).

Strategies implemented at the infrastructure level aim to provide priority to public transportation over other modes of transport. These priority strategies normally fall into one of two categories: those related to facility design and those related to traffic control (Skabardonis, 2000). In terms of facility design, it is clear that the allocation of road space across the different modes (e.g., cars vs buses) is key to the operations of the individual modes (Roca-Riu et al., 2020). Recently developed concepts, such as the three-dimensional macroscopic fundamental diagram (3D-MFD) (Geroliminis et al., 2014; Loder et al., 2017) allow to better understand and quantify the trade-offs between buses and cars, and how they affect the overall performance of a network in terms of vehicle or passenger throughput (Loder et al., 2019). This can be particularly valuable when considering different public transportation layouts (Loder et al., 2019; Dakic et al., 2020a, 2020b), including dedicated bus lanes (DBL) (Jacques and Levinson, 1997; Basso et al., 2011), intermittent bus lanes (IBL) (Viegas and Lu, 2001; Eichler and Daganzo, 2006), queue jumper lanes (Farid et al., 2015), and other types of flexible space allocation between buses and cars (Guler and Cassidy, 2012; He et al., 2018). In general, a higher proportion of managed bus lanes (i.e., those mentioned earlier) lead to more reliable travel times for buses (Arnet et al., 2015). More information about some of these lanes is provided in another chapter. In terms of signal control, it is clear that different algorithms can be used to assign different portions of the intersection capacity to the different modes. Thus, signal control is an important lever to increase the reliability of public transportation. Delays at traffic signals make up 10%–20% percent of the average bus travel times and about 50% of the overall bus delays (Evans and Skiles, 1970). Transit signal priority (TSP), for example, is an inexpensive way of reducing this delay for buses (Smith et al., 2005). TSP strategies are common in cities across the globe, and

Figure 1 Strategies to increase reliability of public transportation vehicles.

they have been well-studied and well-documented for a long time (Levinson et al., 1975). They can be implemented to provide full or adaptive priority (Wolput et al., 2015), take into account the presence of nearby bus stops (Wu et al., 2017), or take into account only schedule-related delays (Yang et al., 2019a). An in-depth review of TSP will be provided in another chapter. More advanced signal control strategies, which can fully adapt to real-time conditions include the use of presignals at intersections with single-lane approaches (Guler et al., 2016), presignals at intersections with multiple-lane approaches (Guler and Menendez, 2014a,b), and bimodal perimeter control (He et al., 2019). More information about these strategies will be provided later in this Chapter in the [Section Adaptive Control Strategies at the Infrastructure Level](#).

Strategies during the dispatching process (i.e., affecting the whole route) can be used to address either changes in traffic conditions along a link and/or demand variations at bus stops. They mostly aim at mitigating bus bunching, a phenomenon related to the instability of the public transportation system (Newell and Potts, 1964). Bus bunching arises when a bus gets somehow delayed, and then it starts encountering more passengers than normal in subsequent stops. These additional passengers increase the dwell time which causes further delays. Simultaneously, the subsequent bus encounters fewer passengers and reduced travel times. Thus the two buses tend to come together (i.e., bunch) as they move along their route. Some dispatching strategies can be introduced during the planning stage and some during the operational stage. They include bus holding (Osuna and Newell, 1972), stop skipping (Vuchic, 1973), and bus substitution and insertion (Petit et al., 2018; Morales et al., 2019). More information about these strategies will be given later in this Chapter in the [Section Adaptive Control Strategies During the Dispatching Process](#).

Last, en-route control strategies (i.e., control strategies at the vehicle level) normally rely on Driver Advisory Systems (DAS), and in the future, could potentially exploit some of the advantages provided by Connected and Automated Vehicles (CAVs). These technologies allow us to switch from infrastructure-based strategies or dispatching strategies to vehicle-based strategies. They can work independently of TSP or other signal control algorithms, yet still provide benefits to buses at signalized intersections. They can also work independently of bus holding or insertion, and bus stop skipping strategies, while still reducing bus bunching. Typical strategies within this category include the optimal speed advisory based on intersection green times (Stahlmann et al., 2018), and vehicle control based on headways or timetables (Daganzo and Pilachowski, 2011). More information about these strategies will be provided later in this Chapter in the [Section Adaptive Control Strategies at the Vehicle Level](#).

As new technologies and information sources emerge, these strategies will undoubtedly evolve, and new strategies will be developed. A brief look into the future is provided in the [Section Future Bus Adaptive Control](#) at the end of this Chapter.

Figure 2 Schematic representation of a presignal at an intersection with a single-lane approach.

Adaptive Control Strategies at the Infrastructure Level

In this section, we focus on advanced signal control strategies that can adapt to real time conditions. In particular, we will focus on the use of presignals (Section Presignals) and perimeter control (Section Perimeter Control).

Presignals

Presignals are additional signals located upstream of an intersection. They are used to provide priority to buses, and can function together with (or independently of) TSP or any other signal control at the intersection itself. They are relatively uncommon in practice, but they are very effective at increasing the reliability of public transportation services. They can be used at intersections with single-lane approaches (Section Presignals at Intersections With Single-Lane Approaches), or with multiple-lane approaches (Section Presignals at Intersections With Multiple-Lane Approaches).

Presignals at Intersections With Single-Lane Approaches

At intersections with single-lane approaches, it is very difficult to provide bus priority. A dedicated bus lane means no cars can use that link, and TSP is not effective if buses get trapped in congestion behind cars in a mixed traffic lane. Thus, presignals are a relatively inexpensive way of allowing the bus to bypass the queue and adhere to its schedule without significantly limiting the movement of cars.

To provide this type of priority, two presignals are placed upstream of the main signal in the travel direction of the bus (see Fig. 2). One of the signals controls traffic in the bus lane (presignal 1), while the other one controls traffic in the opposite lane (presignal 2). Further upstream an additional sensor is used to detect incoming buses. When there are no buses, the two presignals remain green, so traffic moves as usual. On the other hand, when a bus is detected at the sensor location, the two presignals turn red, stopping cars traveling in the two directions. This clears both the bidirectional segment (in the opposite lane) and the lane reentering segment (in the bus travel direction). The goal is for the bus to be able to use the bidirectional segment (or a portion of it) to bypass any queue on its lane, and reenter its lane closer to the main intersection so that it can discharge within a single cycle with minimum delay (Guler et al., 2016). Notice that the signal settings at the intersection do not need to be modified.

The locations and timings of the two presignals need to be carefully designed to make sure that (1) the bus has room to maneuver between presignals 1 and 2 when reentering its lane, (2) all traffic in the bidirectional segment can clear that segment before the bus comes in, (3) the queue created when presignal 2 turns red does not spill back into the intersection, and (4) the bus can skip as much of a queue as possible (Guler et al., 2016). Some of these conditions compete with each other, so a proper setting for presignals at intersections with single-lane approaches must consider those trade-offs. In other words, any implementation should consider both the savings provided to buses as well as the extra delays imposed onto cars, ultimately trying to minimize the total passenger delay across the two modes.

Presignals at Intersections With Multiple-Lane Approaches

In the case of intersections with multiple-lane approaches presignals are used in combination with a dedicated bus lane, especially in cases where the low bus flows do not justify dedicated infrastructure at the intersection itself. The layout and operational strategy in this case are simpler than for single-lane approaches. Only one presignal for the car lanes and a sensor to detect incoming buses in the bus lane are needed (see Fig. 3). This presignal, located upstream of the main intersection, is used to discontinue the dedicated lane so that we can increase the car capacity of the intersection if no buses are present (Guler and Menendez, 2015). As before, the signal settings at the intersection do not need to be modified.

When a bus is detected, the presignal turns red, stopping all car traffic and allowing the bus to maneuver in front of those cars. In this way, the bus can discharge from the intersection within the same cycle with minimum delay. Once the bus passes the presignal location, the presignal can turn green again, if it had been green without the bus. In the case where there are no buses at all, the presignal turns green in advance of the main signal, so that cars can move down to all lanes at the intersection and when the main

Figure 3 Schematic representation of a presignal at an intersection with a multiple-lane approach.

Figure 4 Schematic representation of an area with perimeter control.

signal turns green, cars can discharge using the intersection's full capacity. The presignal should then turn red in advance of the main signal to make sure the area in between the two remains clear of cars for most of the duration of the main red. This way, if a bus arrives, it can move to the front of the queue without any disruption (Guler and Menendez, 2014a).

The location and timing of the presignal must be carefully designed to make sure that (1) the capacity at the main intersection is fully used, that is, the intersection does not starve especially as the main signal turns green, (2) buses can move to the front of the queue as often as possible so they can adhere to their schedule even if the dedicated lane is discontinued, and (3) the queue of cars upstream of the presignal does not grow too long as to spill back into the upstream intersection. As before, some of these conditions compete with each other. Thus close attention should be paid to these trade-offs when designing the system. In particular, presignals for multiple-lane approaches are not effective when the system is close to saturation (Guler and Menendez, 2014b, 2015), as they can lead to very long queues. For varying demands, it is then possible to use adaptive presignals (He et al., 2016) that turn on and off in response to real time traffic conditions, and always aim to minimize the overall passenger delay through the intersection.

Perimeter Control

Perimeter control is used to regulate the inflow of vehicles into a specific area (e.g., downtown). Traffic signals in the perimeter of such area control the rate at which vehicles enter, and this in turn can be used to ensure that the area remains uncongested (see Fig. 4). The idea has gained popularity in the last decade with the development of new macroscopic monitoring and modeling tools for urban networks. Perimeter control can be used instead of dedicated bus lanes under certain scenarios (Section Perimeter Control as a Substitute for Dedicated Bus Lanes) or simply to control the inflow of the different types of modes, providing priority to public transportation (Section Bimodal Perimeter Control).

Perimeter Control as a Substitute for Dedicated Bus Lanes

Although dedicated bus lanes can be very effective for providing priority to public transportation vehicles, they are also rather controversial, as they consume space reducing the available capacity for cars and potentially increasing congestion. Recently, it has been shown that under certain conditions it is possible to maintain the reliability of public transportation vehicles by substituting the controversial dedicated bus lanes with a multiscale perimeter control scheme (Chiabaut et al., 2018). The perimeter control scheme tries to maintain optimal traffic densities within the protected area, while simultaneously reducing delay at the gating

intersections (Yang et al., 2018). This guarantees that buses can move through the network at the desired speeds, yet cars still can use all lanes. While this type of statement still needs more research, it seems a promising direction.

Bimodal Perimeter Control

The idea of perimeter control has become quite popular in the years since the concept of the macroscopic fundamental diagram (MFD) emerged (Geroliminis and Daganzo, 2008). The MFD relates the total accumulation of vehicles in the network to its total throughput. An extension to this concept is the 3D-MFD (Geroliminis et al., 2014; Loder et al., 2017), which relates the individual accumulation of buses and cars in the network to the overall vehicle or people throughput across the two modes. The 3D-MFD allows to better understand and quantify the trade-offs between the two modes as well as their interactions. This opens the door to more advanced perimeter control strategies, that regulate the inflows of the two modes individually (He et al., 2019). It can also be extended to include other priority schemes in the perimeter (Yang et al., 2019b). The overall goal is to maximize the total people throughput in the network.

Adaptive Control Strategies During the Dispatching Process

In this section, we focus on strategies that are related to the dispatching of vehicles. They tend to affect the performance along the whole route or at least a portion of it. These include bus holding strategies (Section Bus Holding), bus stop skipping strategies (Section Bus Stop Skipping), and bus substitution and insertion strategies (Section Bus Substitution and Insertion).

All these strategies can be used independently or in combination with each other, for example, bus holding can be combined with stop skipping (Fu et al., 2003; Cortés et al., 2010). Given that they all have both advantages and disadvantages, they should be evaluated carefully, taking into account the specific settings of the system, before any real implementation. Important metrics to consider include (1) waiting times, (2) commercial bus speeds with (3) the resulting riding times, (4) bus loads, (5) bus trajectories, (6) cycle time distributions, and (7) loss of service for specific passengers. The goal is to increase (2), reduce the average and the variance of (1) and (3), make sure (4) are as uniform as possible across buses (i.e., avoid a mix of full and empty buses), minimize deviations in (5) so to avoid bus bunching (i.e., try to keep headways as constant as possible throughout the route), reduce both the average and the variance of (6) in order to reduce operating costs while maintaining reliability, and minimize (7).

Bus Holding

It is well-known that when buses along a route are not properly controlled, they cannot adhere to their schedule and they tend to bunch (Newell and Potts, 1964). Initial strategies to counteract this phenomenon included holding buses at the dispatching station. This was initially done when no real time information was available (Osuna and Newell, 1972), and then with real time information (Eberlein et al., 2001; Hickman, 2001). With time, these strategies came to include multiple control points along the route (i.e., bus stops) where buses could be held (Daganzo, 2009; Bartholdi and Eisenstein, 2012) (see Fig. 5).

Some of these holding mechanisms were combined with an additional (slack) time built into the schedule so vehicles could catch up, if needed. Slack times reduce the commercial speed of the buses, increasing in turn passenger riding times and potentially the

Figure 5 Schematic representation of bus trajectories with and without bus holding.

Figure 6 Schematic representation of bus trajectories with and without stop skipping.

operating costs. Therefore, they must be relatively small (Daganzo, 1997). These small slack times, when implemented alone, cannot compensate for many system disruptions or a large one (Newell, 1977).

Bus holding can also be combined with boarding limits (Delgado et al., 2012). Boarding limits can emerge spontaneously when passengers chose to wait for the next bus expecting it to have more space. They can also be enforced when the driver asks all passengers or a portion thereof to wait for the next bus.

Bus holding is, in general, one of the most common strategies to mitigate bus bunching, as it is a relatively easy strategy to implement, at a relatively low cost for both the operator and the users.

Bus Stop Skipping

This strategy calls for buses to skip one or more stops along a route. This can be decided in the planning phase to design express services or during real time operations to deal with some disruptions to the system (see Fig. 6).

The idea of introducing stop skipping in the planning phase, offering two types of service (normal vs express), is not new (Vuchic, 1973). It is typically done when there is a high demand associated with specific origin-destination (OD) pairs. It aims at reducing riding times for some portion of the demand, and potentially reduce fleet size requirements. However, for certain frequency settings, it is possible that express services generate more demand than what they can actually handle, leading to additional queues and increased travel times, even when the aggregate capacity of the route is enough (Larrain and Muñoz, 2020).

Bus stop skipping introduced during the normal operations aims to increase the adherence to predefined timetables, or maintenance of the headways. The unpredictability associated with this mechanism can make it an inconvenience for passengers whose origin or destination is skipped. However, even after accounting for that, there are control algorithms that can actually improve the overall system (Sun and Hickman, 2005). As new technologies to share information with the passengers emerge, the use of bus stop skipping strategies will potentially increase.

Bus Substitution and Insertion

Bus substitution strategies are also used to address bus bunching. When a bus is detected to be very late, a new bus (previously in standby) is inserted to take over the schedule of the late bus, and the late bus is marked out of service so it only drops the passengers on-board (does not pick up any new passengers). Once the late bus finishes dropping its passengers, it goes to a standby location or is re-inserted somewhere else along the route (Petit et al., 2018). This strategy is very effective in reducing bus bunching but requires a larger vehicle fleet as some buses must always be in standby.

Alternatively, it is possible to just insert buses without taking any out of service. Similar to the previous strategy, some buses are kept in standby at one or multiple locations along a route. Once a headway is detected to be longer than a given threshold, a new bus is inserted to shorten that headway. For some conditions, this method has been proven to be more beneficial to the system than having the whole fleet of buses constantly circulating (Morales et al., 2019).

In general, bus substitution and insertion strategies can be a very effective way to increase the reliability of the system (see Fig. 7). However, a careful analysis is needed before implementation to make sure they are also cost efficient.

Figure 7 Schematic representation of bus trajectories with and without inserting a bus.

Adaptive Control Strategies at the Vehicle Level

In this section, we focus on strategies that employ DAS (or potentially vehicle connectivity) to regulate the speed profile of a vehicle. These include those related to the timing of the intersection signals (e.g., speed advisory based on green time), and those related to the headways between vehicles or their actual timetables (e.g., to mitigate bus bunching). The former are discussed in the Section Enroute Guidance Based on Signal Timing Information; and the latter are discussed in the Section Enroute Guidance Based on Headways or Timetables.

Enroute Guidance Based on Signal Timing Information

One of the main goals of this type of strategies is to mitigate stop and go maneuvers for buses. Information related to the upcoming signal is given to the public transportation vehicles, so they can better time their arrival at the intersection and reduce the overall number of stops and/or acceleration/deceleration maneuvers.

In the case of speed advisory (Stahlmann et al., 2018), the suggested speed profile for the bus is given based on the phase and timing of the intersection, as well as the actual location of the bus. The goal is for buses to modify their speed, so they can go through the intersection without actually stopping, potentially entering the intersection with a higher speed. In the case of dwell time advisory (Seredynski and Khadraoui, 2014) the suggested dwell times are also given based on the phase and timing of the intersection, and the actual location of the bus stop. The goal is for the buses to wait at near-side bus stops so they can later go through the intersection without stopping. Some of the outcomes might be similar to those of bus holding strategies, but not necessarily.

These two strategies can be implemented independently of TSP, although recent studies have suggested to combine them with some type of priority at the signals (Seredynski et al., 2019). Notice that without TSP or some other type of signal priority, these strategies do not necessarily reduce the delay (as they just move it upstream of the intersection) (see Fig. 8). Combined with TSP, however, they could be used to increase the reliability of the system.

Enroute Guidance Based on Headways or Timetables

Regulating the speed of buses is also relevant for ensuring either constant headway across buses and/or adherence to the timetables. In particular, it can be a very valuable method to minimize bus bunching. Systems running on predefined timetables are typically used to serve low demands, with low bus frequencies (i.e., long headways). Systems serving high demands, with high bus frequencies, normally run on a headway-based schedule.

For public transportation systems that have predefined timetables, automatic vehicle location (AVL) technologies can be used to compare the exact position of a bus at a given time with its target position. This, in turn, can be used to make constant adjustments to the speed along the whole route. Alternatively, for public transportation systems that have a headway-based schedule, each bus can be regulated based on the spacing with the bus in front and the spacing with the bus behind (Daganzo and Pilachowski, 2011) (see Fig. 9). Extensions to this strategy have proven to be useful also for buses following predefined timetables (Xuan et al., 2011), especially when combined with bus holding (Argote-Cabanero et al., 2015). Other applications (e.g., the Transantiago's bus system

Figure 8 Schematic representation of bus trajectories with and without control using signal timing information. TSP refers to transit signal priority

Figure 9 Schematic representation of bus trajectories with and without speed control based on headways or timetables.

in Santiago de Chile) use a combination of a maximum advised speed (so buses can catch up) with bus holding schemes for high-frequency systems (Lizana et al., 2014).

To simplify the enroute speed adjustment process for the drivers, buses can have either a clock that shows how early or late the bus is, a display that shows whether the driver needs to accelerate or decelerate, or a display that shows the maximum speed at which the bus should drive at any given instant. Ideally, buses should maintain relatively constant speeds, and acceleration/deceleration maneuvers should be kept to a minimum.

Future Bus Adaptive Control

Looking forward, new information and communication technologies (ICT), smart infrastructure, and connected and automated vehicles (CAV) hold the promise of more reliable public transportation systems. First, ICT and smart infrastructure could be used to allocate space dynamically to buses while minimizing the disruptions to cars (Wang et al., 2016). Second, these technologies can also be used to develop smarter dispatching strategies, responsive to real time information regarding public transportation demands, as well as traffic information (Dakic et al., 2020c). Third, both the connectivity and computer driving capabilities of the vehicles

could be exploited to easily adapt the speed profile of buses in coordination with optimized signal settings that provide bus priority and take into account the presence of near-side or far-side bus stops, as well as the bus schedules (Yang et al., 2019a). Fourth, ICT and the connectivity across vehicles could also be exploited to predict and minimize the occurrence of bus bunching (Andres and Nair, 2017). In general, we expect that new technologies and information sources not only change the type of vehicles (e.g., to include for example automated modular bus units), but also the flexibility of the system (e.g., to increase coverage and address demand requirements on real time), and its efficiency and reliability (e.g., to react to real time traffic conditions while minimizing both the user and the operator's costs). With all of these resources, both current and upcoming, public transportation planners and engineers have never been better positioned to craft optimal bus services for the benefit of city dwellers everywhere.

Acknowledgments

This work was partially supported by the NYUAD Center for Interacting Urban Networks (CITIES), funded by Tamkeen under the NYUAD Research Institute Award CG001 and by the Swiss Re Institute under the Quantum CitiesTM initiative.

The author also wants to thank Philip Rodenbough and the NYU Abu Dhabi Scientific Writing Program for the feedback on manuscript development.

Biography

Monica Menendez is, since January 2018, an Associate Professor of Civil and Urban Engineering at New York University in Abu Dhabi; and a Global Network Associate Professor at the Tandon School of Engineering in New York University. She is also the Director of the Research Center for Interacting Urban Networks (CITIES). Between 2010 and 2017, Monica was the Director of the research group Traffic Engineering at ETH Zurich. Prior to that, she was a Management Consultant at Bain & Company. She holds a PhD and a MSc in Civil and Environmental Engineering from UC Berkeley. During her studies there she received an NSF Fellowship and the Gordon F. Newell Award. In total, she is the recipient of more than 20 scholarships and awards from well-known and prestigious organizations, professional societies, and universities. Monica also holds a dual degree in Civil Engineering and Architectural Engineering from the University of Miami, from where she graduated Summa Cum Laude.

Her research interests include multimodal transportation systems paying special attention to new technologies and information sources. She is an active reviewer for over 20 journals, and a member of multiple editorial boards for top journals in Transportation. Monica is the author of over 70 peer reviewed journal publications and over 160 conference proceedings and technical reports.

Introduction

Individuals are required to pay a fare to board public transport services which is used to (partially) recover the service costs. This chapter presents a taxonomy, which can be used to characterize a fare collection system of public transport. The presented characterization can be useful for classifying, creating, or modifying components of a Fare Collection System (FCS).

This chapter identifies six components of an FCS including fare structures, fare policies, credit plans, payment methods, ticketing technologies, and equipment. For each component, feasible options are listed and a comparison is made between their attributes. Sections are arranged in such a way that one can understand the key characteristics of a fare structure system and can match a desirable FCS by sequentially selecting the appropriate options from each component. Depending on what has chosen in a previous section, the options in the next section can be selected.

Fare Structures

The fare structure can be divided into two categories: flat (or uniform) and differential (or metered). In a flat structure, passengers pay a fixed rate regardless of their trip characteristics (e.g., Mexico City, Mexico, buses in London, UK, Adelaide and Canberra, Australia, Sao Paulo, and Rio de Janeiro, Brazil). In a differential structure, the fare may vary depending on trip characteristics such as time of day (peak/off peak), start/end location, or distance (TCRP, 2007, 2015, Mezghani, 2008).

The flat structure is easier for the passengers to understand and is more straightforward for the operator to implement than the differential structure. However, the differential structure can better apply the principles of social justice and customer care, as well as adapt a Travel Demand Management (TDM) policy, for example in monitoring and controlling long-distance trips (example distance-base systems in Sydney, Australia, and Amsterdam, the Netherlands; zone-based fares for regional travel in Brisbane, Australia, Dresden, Germany and London underground, UK). **Table 1** summarizes the attributes of flat and differential fare structures.

Another component that affects shaping the fare structure is the management of passenger transfers. The common transfer options include a free transfer (e.g., Hobart, Australia, between rail lines in Washington DC, USA and London, UK), a low-cost transfer, and not recognizing a transfer at all which means separate tickets are required for each and every trip. Transfer management is interconnected with the fare policy which is elaborated in the next section. One should note that all three types of transfer options can be adapted in a flat or a differential structure (TCRP, 2007).

Fare Policies

Maximizing revenue is one of the most important goals of any operator, and is directly related to the number of passengers and the amount of fare charged for each trip. A considerable part of the literature is devoted to studying the variation of demand with a change in the cost of transit trips which is usually carried out by means of mode choice modeling or an elasticity analysis. The operator's revenue is calculated as the net effect of the change in the number of passengers and the fare per passenger. The policies,

Table 1 Attributes of flat and differential fare structures

Fare Structure	Social Justice	Customer focused	Simplicity for managers	Attributes		Income adjustability	Controlling long trips
				Simplicity for passengers			
Flat	Low	Low	High	High		Low	Low
Differential	High	High	Low	Low		High	High

measures, and initiatives that operators use to either influence the number of passengers or adjust the fare usually in order to increase ridership or revenue are called fare policies. These policies may reduce operators' revenue especially when fares are cut and the number of passengers remain unchanged. However, if carefully designed, discount strategies may reduce the fare and increase the number of passengers and thus the revenue.

Examples of these strategies are "discounted fares," which include services designed to encourage a particular group of people such as students or senior citizens to use the public transportation system. Some operators also offer discounts for people using newer payment methods. For example, fare rates can vary depending on paying by a smart card or cash. These discounts may also apply to the specific time of day that public transport has spare capacity; for instance, the fare in off-peak hours may be lower than the peak hours. The off-peak hour discounts are discussed in details in the "credit plan" section.

Some changes in strategies are designed to encourage a higher public transport patronage. The three most commonly used strategies are "free or reduced fare zone," "elimination of fare zones," or "elimination of express/rail surcharge." In the first strategy, some operators introduce free (or discounted) areas such as the Central Business District (CBD) area to increase ridership (e.g., Seattle's downtown in 1973, Portland Oregon in 1975, and Albany New York in 1978). Boarding at the stations of these areas is free or very cheap. At many of these stations, the transit vehicles are crowded. Therefore, removing the fare collection requirement increases facility capacity and improves speed and reliability in these areas which are critically needed. Further to fare collection, inspection of fare is also costly to the operator and can be detrimental to the service performance.

In the case of "elimination of fare zones" or "elimination of express/rail surcharge," some costs such as a surcharge at peak times or a surcharge due to the use of express/rail services are removed or reduced. The abovementioned strategies can be effectively implemented in a differential fare structure because of its embedded flexibility. Within the differential structure, it is possible to define different fares at different times, stations, routes, and days, while in the flat fare structure, fares are already fixed and flat (TCRP, 2007).

Some strategies are easier to implement in a flat structure such as reducing the base fare. The base fare is the minimum price that is charged to every passenger regardless of the time of day and usage duration. This strategy is not common, and if not supported by sufficient studies, may incur a significant loss to the relevant service operators.

If the transfer charge is already low, a less-risky approach is the simultaneous implementation of a low-cost fare scheme and the elimination of a free (or a low-cost) transfer (see the fare structures section). Although eliminating the free transfer is easy to implement, it can also lead to a decline in the ridership (depending on the reduction amount in the base fare and the number of transfers) and reduce operator's revenue.

In the case that the current transfer charge is already high, a "transfer price reduction" strategy can be adapted to attract passengers. Removing or reducing transfer charges are easier in systems that issue one ticket for an entire trip (usually on boarding) or use electronic methods (see "payment methods") since the transfer charge can be deducted from the total fare when calculated by the system (TCRP, 2007). A partial removal of transfer charges is also possible when the "same mode transfer" is made free. Examples are train-train or BRT-BRT (Bus Rapid Transit) transfers since passengers can move in a close system without passing a payment gate to transfer within the same mode. Another common option to reduce (or remove) transfer charges is using a *duration-based* ticket. Hourly or daily tickets are examples of such an option by which passengers can travel for as many times as they want during the designated period. The complete range of duration-based tickets are reviewed in the "credit plans" section.

Credit Plans

General Credit Types

There are various types of credits issued for transit tickets. Each transit operator offers a range of tickets depending on the history of the ticketing system and how it is evolved as well as the existing "fare structure" and "fare policies." These credit plans can be classified to three general categories of duration-based, trip-based, and value based plans.

Duration-based tickets are travel permits for the validation period of the ticket. Unlimited trips are possible during this validation period which can be as short as one or two hours to a day or even to a few months. Common types are hourly tickets (usually two hours), daily, weekly, and monthly tickets. A longer period such a six-months or a yearly pass also fall in this category. These tickets can be activated from the moment of purchase or the first transaction. The use of this type of credit became more prevalent with the introduction of electronic payment options which is reviewed in the "ticketing technologies" section (TCRP, 2007, 2015).

Contrary to a duration-based ticket for which the time to use the ticket is limited, the other two types of tickets put a limit on the number of trips or the fare value itself. A trip-based ticket allows one to make a certain number of trips, but without limiting the time of those trips. Common types are return tickets (two-way tickets), ten-trips or the like. This type of ticket can be an attractive option for people who use transit without a fixed schedule or make long-distance trips in a differential fare structure. Value-based tickets provide passengers with a credit to pay in a complex fare structure. By using the ticket, the trip cost will be deducted from the available credit. A common type of this ticket is the smart card technology that attributes a credit value to the card and adjusts it with each transaction. Duration-based and trip-based credits are more compatible with a flat fare structure while the value-based credit can better be adapted in a differential fare structure.

The above credit types can be combined in one ticket too. For example, combined duration-based and value-based options are one of the types of tickets that can operate in a multimodal system. In the metro network, the cost can be paid by credit based on zone and distance, and on the local buses based on time. In other words, from the passenger's perspective, one ticket is used in all modes but the operators may charge it as a duration-based, trip-based, or value-based (TCRP, 2007, 2015).

Special Tickets and Credits

In addition to the above categorization, credit plans and respective ticket types can be viewed from other aspects including off-peak tickets, group tickets, special event tickets, special strata tickets, tickets promoting a specific ticketing technology, and advanced pattern-specific promotions.

Off-peak tickets are offered at a cheaper rate during the off-peak periods when the transit vehicles are less crowded. These types of tickets may encourage people to travel at specific times of the day, weekends, or a combination. Where more than one type of off-peak ticket is offered, cheaper tickets have more restrictions. These cheaper tickets are sometimes called super off-peak (National rail of UK, 2019).

Another type of special credit ticket is a group ticket. A group ticket is a discounted ticket that some transport operators offer to a group of passengers traveling together. These discounts are mainly offered during the off-peak times, and the carrier determines the minimum and the maximum number of the group members that can receive this type of ticket.

A special event ticket is offered in conjunction with other purchased services (such as sports matches, community festivals, fairs, and off-site parking areas) to allow a convenient access to the destination by transit, rather than using a personal vehicle. Special event tickets are not only a Transport Demand Management (TDM) strategy to mitigate crowding of a big event, but also an opportunity to attract new customers to the transit system who do not use transit in their weekly routine.

Special strata tickets are offered to a special sociodemographic class of citizens. The common strata are children, students, and senior citizens/pensioners. Special strata tickets can easily be incorporated into credit plan categories of duration-based, trip-based, and value-based either by issuing a special strata ticket or when a credit is loaded to the ticket.

The next aspect on the credit plan is its capability to promote a ticketing technology. A variety of discounts and concessions are proposed to encourage passengers to buy a *fare card* (see "ticketing technology"). One of the most common of these concessions is that the fare card is preloaded with an initial credit. Second and more importantly, the fare can be cheaper if paid by a fare card compared to cash. Third, a guaranteed last ride (or a negative balance) can be included in a ticket. In this case, if the passenger's fare card does not have enough balance to pay for the trip, a negative balance is registered to enable the passenger to make the trip. The passenger should load the card for future trips. One reason to promote a fare card over cash is the higher efficiency of fare payment by a fare card since the average boarding time by a fare card is much shorter than by cash. This reduces vehicle dwell time at stations and can potentially increase transit facility capacity and speed (TCRP, 2007).

There are other advanced options available that are specific to some trip patterns. One of these pattern-specific options is refunding the passengers for a partial cost of their trip. The refund is loaded as credit to encourage them to make more trips within a certain period of time. This bonus credit can expire after a defined period if not used. A similar option is offering free trips if the number of trips exceeds a given threshold in a week (also called a frequency-based discount). A third example is called a "guaranteed lowest fare" plan which is applicable to a fare system that offers multiple promotions such as off-peak, frequency based, or special event tickets. The guaranteed lowest fare ensures that passengers are charged the minimum amount while considering the combination of all promotions. A value-based fare structure enables operators to design complex marketing schemes such as the above pattern-specific promotions to increase ridership and revenue.

Any of the duration-based, trip-based, and value-based credit plans to some extent can adopt the options of off-peak tickets, group tickets, special event tickets, special strata tickets, tickets promoting a specific ticketing technology, and pattern-specific promotions.

Payment Methods

This section reviews the fare collection options and defines its relation to the fare structure, credit plan, and ticketing technology. Payment methods can be classified with respect to place, time, and mode of payment as depicted in Figure 1.

In terms of place of payment, passengers may pay before boarding (off-board) or may pay in-vehicle after boarding (on-board). The method of payment and the technology used have an important effect on the capacity of a transit facility as well as other performance indicators (TCRP, 2017). Thus, depending on the transit authority's policy and the available budget, the best payment

Figure 1 Classification of payment methods.

Table 2 Payment modes and their properties

Mode	Passengers	System/Operator
Tap on/tap off (TOTO)	Presenting tickets (active)	Checking tickets (active)
Proof-of-payment	Not presenting tickets (passive)	Not checking tickets (passive)
Be in/be out (BIBO)	Not presenting tickets (passive)	Checking tickets (active)
Not an available mode	Presenting tickets (active)	Not checking tickets (passive)

method can be selected. Each of the payment methods have their own advantages and limitations. In general, off-board payment methods enable the transit facility to offer a faster boarding and thus a higher capacity than the on-board methods. In return for the high capacity, the off-board methods occupy a larger station space in which the fare collection equipment should be installed. Having the equipment installed at stations, reduces the flexibility of the transit line to relocate stops. As for the on-board method, monitoring the payment is challenging if multiple doors are available and boarding is allowed from all doors (such as the case of a tram/streetcar). Both payment methods can be implemented in a flat or a differential fare structure.

In terms of payment time, the boarding, in-vehicle, and alighting phases should be considered. Some systems may need to check passengers on entry, on exit, on both, or neither. If a flat rate is charged (i.e., a flat fare structure), it is sufficient to check the fare on entry (called pay-on-entry) or on exit (called pay-on-exit) while the former is more common around the world (Currie and Reynolds, 2016). If a differential rate based on distance or zones is charged (i.e., a differential fare structure), passengers should be checked on both entry and exit to calculate the fare. There is a special payment system that does not require passengers to present their ticket at all, which means neither at the entry nor at the exit. Proof-of-payment allows passengers to acquire a form of ticket and to carry it at all times onboard. The operators only use random checks by a few inspectors to enforce ticket purchasing. Pay-on-entry, pay-on-exit, or differential payment which requires checking at both entry and exit, can happen off-board or on-board.

The mode of payment divides the payment methods to “tap on (or check in)/tap off (or check out)” (TOTO or CICO), proof-of-payment, and “be in/be out” (BIBO) based on what roles are played by the passengers and the fare collection system. TOTO is when passengers need to present their ticket actively and the system checks all tickets. Proof-of-payment does not require passengers to present their ticket nor the system to check all passengers. Only random checks may be performed by inspectors. The third mode of payment is BIBO in which passengers do not present a ticket actively, but the system checks all passengers using the BIBO technology (e.g., in Dresden, Germany). Special gates at the entry and/or exit points monitor whether or not passengers carry a valid ticket without asking them to take the ticket out of their pocket. Since it does not make sense for the passengers to present the ticket actively but for the system not to check the tickets, a fourth type of payment mode is not defined (TCRP, 2015). Table 2 summarizes these payment modes and their properties.

A “tap on” or “be in” is utilized when a pay-on-entry fare is charged. Similarly, a “tap off” or “be out” corresponds to pay-on-exit. It is also possible to have a hybrid system with “tap on” at the entry and “be out” at the exit. A TOTO or a BIBO matches a differential fare structure when both entry and exits are to be recoded.

Ticketing Technologies

In decades, various technologies have been developed to collect transit fares. Implementation of an efficient fare system relies on choosing the right ticketing technology. Some of the capabilities listed in the previous sections can only be expected from a certain technology. In this section, a wide range of technologies are reviewed to enable the transit agencies to assess them in conjunction with the agency's goals and objectives, technology availability, and budget. This section covers from traditional methods of cash, paper ticket, and ticket token to more modern tickets of magnetic cards, smart cards, Radio Frequency Identification (RFID), Near Field Communication (NFC), Short Message Service (SMS) tickets, QR code tickets, and smartphone ticketing.

- Paper ticket and cash: The fare could be paid by purchasing a paper ticket or a token before boarding and presenting the ticket to ride a transit vehicle. Alternatively, the fare could be paid by cash to board. Paying cash increases the boarding time compared to a paper ticket since the station or vehicle operator may need to return a change. These traditional methods work well with a flat fare structure although examples of systems accepting cash in a differential fare structure exist around the world (e.g., Brisbane, Australia). A cash accepting system is especially convenient for tourists given that they can readily board a transit vehicle without prepurchasing any form of ticket.
- Magnetic card: Magnetic cards are a simple paper (or plastic) card with a magnetic strip which make a transaction when passed through a reader slot. Magnetic cards generally come in two types: read only and read & write. The credit of read-only cards are set when issued and the credit can only be deduced from them. They can be used with the "credit plans" of duration-based and trip-based. Read & write cards can be used with all "credit plans" including a value-based plan given that credit can be deduced or added on them. Although magnetic cards are a relatively cheap ticket to produce, they are not durable and can easily malfunction if folded or exposed to a magnetic field. These cards were introduced in periods on the London underground and the Long Island Railroad (Mezghani, 2008, TCRP, 2015).
- Smart card: These fare cards have an electronic chip in them that can store and encode a considerable amount of information such as the card holder's identity, credit value, and trip history. The three main types of smart cards are contact, contactless, and proximity (BIBO) cards. The contact cards need to be inserted into a reader while the contactless cards can be read when placed closed to a reader (a range of 5 cm). Proximity cards can be read when the card holder is in the vicinity of its special reader (a BIBO reader). Proximity cards can also work as a contactless card if a special BIBO reader is not available. (The World Bank, 2011, TCRP, 2015, Faroqi et al., 2018, Mezghani, 2008). Both magnetic and smart card technologies can cover a variety of credit options. However, magnetic cards are cheaper than smart cards, but their reader equipment is more expensive to maintain. The storage and processing capacity of smart cards are significantly higher than magnetic cards. Generally, magnetic cards are easier to sell, while smart cards are easier to use (Mezghani, 2008).
- RFID (Radio Frequency Identification) technology: RFID tags fares are functionally similar to proximity smart cards since both can be read when placed in the vicinity of a reader/gate. However, RFIDs are mainly Read-only, and their radio-based barcodes are mostly used for identification. They are cheaper, have much less memory, and are smaller in size than smart cards. However, smart cards are more secure than RFID tags. (Octopus cards in Hong Kong) (Mezghani, 2008).
- NFC (Near Field Communication) technology: The NFC technology allows an electronic device to communicate with a reader in a short range of 2–10 cm. Similar to a contactless smart card, the exchange of data is contactless and can happen in a short range. NFC can perform a two-way transmission between the reader (receiver) and the device (transmitter). The technology is powered and is already installed on some smart devices, especially smart phones. This enables NFC to be programmed by smartphone apps, while smart cards and RFID tags are unpowered and rely on the master device for any interaction (Secure Tech Alliance, Chandler, 2014).
- SMS (Short Message Service) tickets: Short Message Service (SMS) is a standard communication service on the fixed and mobile phones. A SMS ticket can be issued upon request from the ticketing server by an SMS text or an Unstructured Supplementary Service Data (USSD) service. The text can be used as an electronic travel document to be presented to the transit ticket inspector (Florida Department of Transportation BDV, 2016).
- QR Code tickets: QR code is a two dimensional barcode that can encode some information. The ticket information (e.g., its value and validation time) can be converted to a QR code and given to a passenger on a smart device or printed on paper. The QR code reader, by reading this code, can access the stored information and allow an entry. QR Code tickets can be issued by web services, smartphone applications, and ticketing machines.
- Smart phone ticketing: In addition to NFC, SMS, and QR code that are available on smartphones and some other media, some ticketing options are exclusive to smartphones since they have integrated abilities of processing power, a large memory, and network connection means. This allow travelers to book trips and get tickets through smartphone applications (e.g., the contactless card or smart phone cashless buses in London) (Florida Department of Transportation BDV, 2016). A specially interesting case is the emerging concept of Mobility as a Service (MaaS). Passengers may purchase their tickets from a MaaS smartphone application and present it to board a service if the transit infrastructure accepts one of the available technologies on smartphones. For more information on MaaS please see the MaaS Entry (Florida Department of Transportation BDV, 2016).

Equipment

A fare collection system requires equipment to issue a ticket, collect a ticket, and recharge users' accounts. The type of this equipment is determined by the ticketing technology, the payment method, and the fare structure. The equipment is a part of the transit infrastructure system and plays a key role in the quality of services provided to passengers. Equipment types are as follows:

- Ticket vending machine: It is a device that sells tickets and if applicable, recharges passengers' tickets. Depending on the type of ticketing technology, vending machines offers compatible services to passengers. These devices are usually placed in main transit stations.
- Online ticket service: with the dominance of web-based and mobile ticketing systems, online sale of tickets is an emerging venue. A notable example in this area is Software as a Service (SaaS) which is a business model to contract with a transit operator to arrange the sale of tickets through a standard mobile application. The vendor usually receives a portion of sales in return for the service.
- Fare box: A device at the station (off-board payment) or in-vehicle (on-board payment) that is used by passengers to pay the fare.
- Fare gate: A fare gate requires passengers to validate their ticket before they are allowed to pass. A fare gate is usually used off-board and is compatible with magnetic card, smart card, QR code, and smart phone ticketing.
- Fare gantries: A fare gantry allows passengers to seamlessly get through the gantry and automatically pay the travel fare. It is a replacement for a farebox or a fare gate and is compatible with a BIBO payment method. It can be applied in off-board and on-board systems.

Integration of Fare Payment

A transit network in a conurbation may have several modes, operators, or even jurisdictions. On a daily commute, one passenger may use multiple services across those divisions but it is inconvenient for passengers to acquire multiple tickets. From the passengers' perspective, a door to door mobility service is expected and it is not important how it is operated and managed in the background. Therefore, many transit authorities offer an integrated fare payment system that mediates between the passengers and the operators (or even jurisdictions). The integration is made possible with the advent of new ticketing technologies such as smart cards and smartphone ticketing. However, integration of a fare system does not mean integrating all of its components. With a flexible fare system, operators can partly retain their own fare structure, credit plans, or even payment methods (see the respective sections above). However, a consistent ticketing technology and equipment should be used. For example, using a smart card (the same ticketing technology) and a set of fare boxes and fare gates (the same equipment), passengers may pay a flat fare on buses but a differential fare on metro (different fare structures) (TCRP, 2007).

Integration of fare payments provides passengers with a higher convenience in purchasing and presenting tickets, easier transfers, and increased capacity, speed, and reliability for the services due to shortening the dwell time and its variability. The operators also benefit from the integration since a higher patronage leads to an increased revenue, a higher capacity, speed, and reliability can reduce operating costs and increase passenger satisfaction. The general public would also benefit from the potential congestion relief, environmental improvements, a better quality of life, and economic efficiency resulted from an improve public transport system with a higher patronage.

Conclusions

In this chapter, a transit fare collection system is characterized by identifying six components namely fare structure, fare policy, credit plan, payment method, ticketing technology, and equipment. The goal was to present an inclusive taxonomy which provides a unified basis to compare existing and future fare collection systems. The six components are presented in order, that means a reader should first determine the fare structure (flat or differential), then the credit plan (duration-based, trip-based, or value-based) and the payment equipment (off/on-board, pay-on-entry/exit, TOTO/proof-of-payment/BIBO). After that, the ticketing technology (from paper tickets to smartphone apps) and the equipment (from a humble farebox to fare gantries) are to be defined. The final remarks highlighted the importance of moving toward an integrated fare collection system in which passengers can travel seamlessly.

Path choice route taken by the passengers to minimize their travel time during the journey

RTTIS real-time transit information systems. They include all types of transit information providing systems such as RTI display boards, web-enabled services and mobile devices

Ridership the number of passengers using a particular mode of transit

RTI S Display Boards used to provide real-time information to passengers through display boards at transit stops and stations

Transit providers agencies or organizations which facilitate the transit services

Introduction

In the present digital era, technological advancements are promoting the transit industry across the world and assisting the passengers by providing appropriate transit information (such as route details, traffic conditions, schedule of availability, time and fare details). Transit information enables the users to make travel choices according to their suitability. The effectiveness of “transit information system” relies on the availability of real-time information about the position as well as prediction of arrival time of the transit mode at a particular place of access or station. The real-time transit information (RTTI) can be distributed in various forms such as mobile phones, roadside kiosks at stations and dynamic message signs (DMS). Due to the information and communication technologies (ICT)-based dissemination of real-time transit information to the passengers, they can access the transit details at anytime and anywhere during their travel (Papangelis et al., 2013). It has made travel flexible as travel decisions can be taken/modified at any stage of the trip (i.e. pre-trip, en-route, and post-trip) since the transit information acquisition in real time is possible.

Factors Influencing the Transit-Oriented Decisions of Passengers

Fig. 1 shows the complex links between the various factors influencing the behavioral responses of the travelers (Zhang, 2010). Along with the real-time transit information obtained from the transit service providers, demographic factors (such as age, income, car ownership, etc.) and situational factors (such as weather, environment, etc.) influence the transit-oriented behavior/decisions of the passenger as well as their psychological responses. The positive attitudinal changes and positive perceptions toward transit services are advantageous to the smooth functioning of transportation systems. For these positive changes to occur, travelers might be able to obtain the real-time information easily, and subsequently the obtained information would lead to favorable psychological and behavioral results.

Figure 1 Factors influencing the traveler behavioural responses (Zhang, 2010).

Information Demand–Supply Trade-Off of RTTIS

The efficiency of transit information systems would be maximum when the information demand of passengers meets the information supply from the transit providers (Velaga et al., 2012a). With respect to information dissemination to the passengers, dynamic message signs (DMS) were found to be the most popular among the different methods in Ireland (Caulfield and O'Mahony, 2007). They also observed that the use of RTTIS increased with the increase in trip complexity. A study in Germany investigated the gap between information demand and supply by interviewing the transit service providers and conducting a survey among the passengers (Beul-Leusmann et al., 2013). They found that majority of the passengers rely on websites to obtain real-time information with respect to transit services, and also criticized the methods of providing transit-related information by the transit providers. Research on the information supply side showed that factors such as agency size, demographics, modal service and increasing competition in the market influenced the information dissemination to its customers. Other reasons that were observed over time were lack of funding and technical expertise (American Public Transportation Association, 2015).

However, information demand and supply preferences are likely to change with time and growth in technology. A recent study in the United States examined the user preferences in the information demand and identified the most preferred type of information required by the passengers, along with preferred medium of information dissemination (Harmony and Gayah, 2017). Furthermore, the extent to which the transit providers were able to satisfy the passenger needs was investigated along with the reasons for the differences observed in demand and supply of transit information. The observed comparisons of information demand and supply are summarized in Table 1 (Harmony and Gayah, 2017). The first column in the table lists out the information demand of the

Table 1 Comparison of transit-related information demand and supply (Harmony and Gayah, 2017)

Information type	Comments	Adequately meets needs?
Arrival/departure times for next vehicle	The most desired type of information by passengers is the best provided information by agencies	Yes
Real-time location of transit vehicles	- Information well provided for in many different ways - Highly valued by passengers and provided by many agencies - The two most desired mediums for providing information are the two best supported mediums provided by agencies	Yes
Seating availability	- Relatively low importance for passengers but more important for bus passengers; hence too few agencies offer information - More information needs to be offered on smartphones and DMS	No
Number of cars on next train or type of next bus	- One of the least valued types of information and least provided by agencies - Information is provided through multiple platforms when it is available	Yes
Real-time trip planning	- Very important to passengers and many agencies provide information - Well provided for in most desired mediums for providing this information	Yes
Information for planned detours and special events	- Very important to passengers and many agencies provide information - More information needs to be provided on DMS	No
Identification of unplanned service disruptions	- Very important to passengers and many agencies provide information but more need to do so - More information needs to be provided on smartphone applications	No
Emergency information	- Somewhat important information that is well provided by agencies - Needs to be better provided on DMS	No
Information on availability and operational status of elevators/escalators	- Lower importance by passengers but it is relatively well provided by agencies - Information needs to be better provided for on smartphone applications	No
Parking availability	- One of the least important types of information and least provided by agencies - Information needs to be better provided for on smartphone applications	No

passengers. The second column describes its order of preference/priority and the third column reports whether these information demands are satisfied by the transit providers. It was found that information related to the arrival/departure times of transit vehicle was the most desired information by the transit users; whereas information on seating availability in the vehicle was the lowest desired information (Harmony and Gayah, 2017). With respect to the medium of providing information, smartphones were the most preferred medium followed by websites and dynamic message signs. The comparison presented in Table 1 showed that the transit-related information supply by service providers is mostly in consensus with the priority of information demanded by the passengers (Harmony and Gayah, 2017). Nevertheless, some information gaps exist which are required to be bridged with time to improve the transit efficiency. These gaps may be identified as the information with respect to seat availability, emergency information, details about any detours, availability of elevators, etc. The implementation of RTTIS can be improved by maximizing the public involvement by considering their feedback about their experience and issues faced, along with working on the alternative sources of providing information.

Key Impacts of Transit Information Systems on Travel Behavior

RTTIS is known to influence the travel decisions of commuters, thereby impacting the decision to undertake a trip, to select a preferred mode of transit over the other modes, and to select a designated path to reach the destination. Moreover, it also affects the decisions to board the transit as well as alight from the transit during the trip. All these decision-making procedures with respect to RTTIS can be compiled in a trip choice framework from the user perspective as presented in Fig. 2. The framework shows the various influencing factors and behavioral outcomes which are likely to be influenced by RTTIS services (Brakewood and Watkins, 2019). All of them are discussed in detail in the subsequent sub-sections.

Waiting Time/Travel Time

The large body of research shows that RTI display boards reduce the perceived waiting time; whereas, RTI facilities provided through personal devices reduce the perceived as well as actual waiting time since the users can stay at their place of residence or work, and leave to their pickup stop when the transit facility is about to arrive (Velaga et al., 2014). The relationship between the RTTIS and the waiting time of riders have been examined in various studies (Brakewood et al., 2014; Dziekan and Vermeulen, 2006; Watkins et al., 2011). A study by Watkins et al. (2011) investigated the perceived waiting times of RTI users and non-RTI users at bus stops in Washington (USA), and reported that self-reported average waiting time for RTI users was 30% less than the riders who did not use RTI facilities. Another study by Dziekan and Vermeulen (2006) in Hague (Netherlands) analyzed the change in waiting times of passengers at a tramline before and after the installation of RTI systems. They found about 20% decrement in the waiting time of passengers after the RTI system was installed.

The passengers tend to select the shortest path from their origin to destination; this information about the optimum path choice (or route choice) can be obtained using RTTIS facilities. These facilities are more useful in cases where transit services do not comply with a particular fixed schedule. In such cases, passengers can use RTTIS and make a decision of selecting an alternative mode/route of transit if the scheduled mode/route is not available. The extent to which RTTIS influence the path choice and associated travel time of passengers has been studied in past (Cats et al., 2011; Estrada et al., 2015; Hickman and Wilson, 1995). A simulation study in Uruguay revealed that RTTIS has the potential to reduce the total travel times up to the extent of 45% compared to unavailable time

Figure 2 Influence of RTTIS on transit service (Brakewood and Watkins, 2019).

schedules of buses (Estrada et al., 2015). A study conducted in Sweden on subway transit service reported that implementation of comprehensive RTTIS facilities resulted in savings in total travel times (Cats et al., 2011).

The research indicates that savings in total travel time of passengers using RTTIS services range from 3% to 45%. However, there is huge scope of conducting future research where travel time reductions can be analyzed with different frequencies of transit service, and different levels of network coverage and route options (such as sparse networks versus dense networks).

Transit Use

Due to the implementation of RTTIS applications, reduced waiting times and efficient route choices minimizing the total travel time would eventually lead to an increased use of the transit mode. Moreover, new riders may also be attracted toward the use of the transit systems. Various researchers had observed significant increase in the ridership of RTTIS users in transit vehicles such as buses and trains (Ferris et al., 2010; Ge et al., 2017; Gooze et al., 2013; Politis et al., 2010). After the installation of RTI display boards on an office building in Seattle, transit users were found to increase by about 4% (Ge et al., 2017). With respect to RTI services provided on personal devices, 30% users reported higher frequency of noncommute trips and 10% reported higher commute trips (Ferris et al., 2010; Gooze et al., 2013). Another study in Greece observed 19.7% of the people mentioning that they have made new trips after the implementation of RTI display boards (Politis et al., 2010).

Some survey-based studies reported that significant proportion of respondents would like to increase the frequency of transit use if the RTTIS services are provided at transit stops/stations (Tang and Thakuriah, 2011, 2007). A stated preference survey was conducted in Chicago (USA) before the implementation of RTTIS, where about 76% of the participants were willing to increase their use of transit when the RTTIS services were provided (Tang and Thakuriah, 2011). In a survey-based study, it was reported that 67% of the participants were willing to increase the frequency of transit use if the transit stations were equipped with RTI display boards (Tang and Thakuriah, 2007). However, several other studies did not find any significant impact of RTTIS services on the increase in transit use (Brakewood et al., 2014; Zhang et al., 2008). A major limitation observed in the past studies is that they are mostly focused on larger cities such as Chicago, New York and Seattle. Future investigations are required to emphasize on medium and small-scale cities to examine the influence of RTTIS on transit use among the existing users as well as the new users.

Perception of Safety and Personal Security

As RTTIS enables the commuters to devote less time for waiting at transit stops/stations, it is likely to increase the perception toward safety and personal security while using transit facility, especially during night time. A behavioral study on passengers using a bus as a transit mode in Tampa, USA reported that safety perceptions were significantly higher for RTTIS users with respect to the control group during day time. However, no such significant increment in perceived safety was observed during night time (Brakewood et al., 2014). Alternatively, a study in the University of Maryland, USA reported statistically significant positive influence of RTTIS on personal security feelings during night time, but no such significance was observed during daytime (Zhang et al., 2008).

A few web-based surveys enquired about the safety perceptions of RTI users. A study by Ferris found that 21% respondents felt safer by using RTI facilities on their personal devices (Ferris et al., 2010) while the other study reported 32% of the users with increased safety perceptions (Gooze et al., 2013). Another study in Hague, Netherland analyzed the passengers' security ratings (on a scale of 1 to 10) at tram stations, and observed no significant difference in the security ratings before and after the implementation of RTI display boards at the stations (Dziekan and Vermeulen, 2006).

Personal Satisfaction with Transit Service

Reduced travel times and waiting times at transit stations due to RTTIS may also lead to increased individual satisfaction with the transit service. The effects of RTTIS on personal satisfaction with transit services had been widely explored by various researchers (Brakewood et al., 2014; Ferris et al., 2010; Ge et al., 2017; Gooze et al., 2013; Zhang et al., 2008). However, the literature has observed mixed findings with respect to personal satisfaction, where majority of the studies reported significant increase in personal satisfaction with transit service after RTTIS implementation (Brakewood et al., 2014; Ferris et al., 2010; Gooze et al., 2013; Zhang et al., 2008) with an exception of a study which observed decrease in personal satisfaction after RTI services were provided (Ge et al., 2017).

Psychological Effects of RTTIS on Ridership

The influence of Real-time transit information systems (RTTIS) on the ridership are generally studied by comparing the transit ridership statistics prior and post implementation of transit information systems. The ridership effects have been observed positive on the routes where RTTIS was implemented. However, analyzing the before and after effects of RTTIS may not be sufficient to successfully predict the variations in ridership as it depends on various factors such as transit fares, fuel price, population changes, etc. which fluctuates with time and may influence the ridership.

Positive psychological effects of RTTIS have been observed on the commuters, such as reduced anxieties, higher safety perceptions, and higher satisfaction levels. To investigate the effects of cognitive psychology (i.e., attitudinal and behavioral factors) along

Figure 3 Relationship between attitudes, behavioral intentions and travel behavior (Tang and Thakuriah, 2011).

with transit service-related factors and socioeconomic factors on ridership, researchers have developed conceptual frameworks, such as one shown in Fig. 3 (Tang and Thakuriah, 2011). Their findings suggested that RTTIS is successful in increasing the transit ridership and has potential in serving as an intervention for breaking the travel habits of transit nonusers', thereby increasing the transit use mode share. Passengers' attitude toward travel time is a significant factor influencing the psychological decisions related to the use of transit service. Moreover, past experience with RTTIS also influences their intentions of using the transit service. Therefore, by incorporating methods which enhance the exposure of RTTIS facilities to the commuters to familiarize them with the usage, it can prove to be even more beneficial. Also, the information provided to them should be easily understandable, effortlessly digestible, more importantly reliable, and should be able to answer the demands of commuters.

Social Effects of RTTIS

RTTIS improves the accessibility to transit services for individuals with disabilities and empowers them to be independent and enhances their quality of life. Since disabled people have various physical and environmental constraints, use of emerging technologies helps them in adapting to the smoother way of travel. Especially, the increasing use of smartphones has resulted in increased use of transit related applications which provide real-time information related to transit services to the users. These applications use the smartphone location and provide an estimate on the expected time of arrival or departure of the transit. Consequently, they are quite useful for the disabled population as well; however, use of these applications demand the users to be well-equipped with the use of technology. In a recent report on accessibility of disabled population in the United States, it was found that the count of commuters with certain disabilities using public transit increased rapidly compared to the other non-disabled users during 2005–2015 (National Council on Disability, 2015). However, more efforts are required to provide supplementary disabled-friendly services with special emphasis on the disabled population which is likely to reduce the accessibility barriers and assist them during their travel.

Technological Advancements in Transit Information Systems

Ridership data related to origin and destination of trips are important for transit agencies to understand the travel patterns of transit users. One of the widely used methods to obtain this information is through linking open data and crowdsourcing with the help of smartphone-based applications (Corsar et al., 2017; Traut and Steinfeld, 2019). The ridership data is collected when the transit users select their place of origin and destination, along with transit stops, and available mode while using the applications. Moreover, the origin-destination and transfer data of transit users can also be extracted from the smartcards which are used for the purpose of automated fare collection (Pelletier et al., 2011).

Conclusions and Directions for Future Research

This chapter provides a distinguished review on the impacts of real-time transit information systems on passengers, their travel behavior and ridership. On one hand, the positive sides of RTTIS makes transit easier and comfortable for the commuters; on the other hand, the information demand-supply difference exists which needs to be bridged in order to improve the efficiency and effectiveness of the overall transit system.

Various stakeholders are indulged at each stage of providing real-time transit information (RTTI) to the users, i.e. during the development, dissemination and operation stages. These stakeholders decide the nature of information demand (i.e. what information is required by the users) and information supply (i.e. what information needs to be provided to the users). However, researchers have examined both the information demand and information supply separately; therefore, the investigation on trade-off between the demand and supply of information may serve as a scope for future research. Furthermore, the comparison of user benefits from RTTIS with the transit service provider costs of providing RTTIS (i.e. cost-benefit analysis) is an interesting area for future research. Another direction for future research could be to investigate the situation-wise impacts of RTTIS on the transit ridership, for instance, with increasing transit frequency and service availability. With increasing usage of smartphone applications for connecting to transit service providers, the users provide their location data from which their travel patterns are estimated. The influence of travel behavior of commuters on the area-wise real-time traffic crowding/traffic calming has scope for future investigations.

Uber transit is a recent feature provided by the Uber in various cities around the world, with the aim to improve the accessibility of public transit by providing real-time information of the availability of the transit service at nearby transit stops. For instance, in the city of Denver, Uber riders can plan their subsequent transit ride by following the directions available in the Uber app. This integration of public transit information in the applications of aggregator taxi services is a positive step toward the increased use of transit service; however, the influence of such technology on the transit ridership shall be an important area for future investigations.

Introduction

Trams are light rail transit vehicles, which run on fixed rail tracks on roads and mostly share the road space with other traffic and pedestrians. The term “streetcar” used in North America share the similarity of the tram system in the rest of the world. Tram systems have a number of attractive features including their high passenger capacity, good comfort, and very low emission of pollutants compared to other transport systems. Therefore, many cities and countries are extending their tram networks as well as introducing new networks to reduce traffic congestion and to improve the urban environment.

Trams sharing the road with general road traffic is often known as “mixed traffic tram operation.” Mixed traffic tram operation is the least desirable operational type due to the impact of road traffic on tram travel time and reliability (Vuchic, 2007). Melbourne has the largest tram network in the world and it includes the largest mixed traffic tram network with a track length of 167 km (100 miles) (Currie and Shalaby, 2007). The majority of streetcar routes in Toronto also operate in mixed traffic, which is the second largest mixed traffic tram operation. Many cities and countries are implementing tram lane priority measures on road corridors with an aim to transform mixed traffic tram or streetcar system to a light rail comparable service “as far as practical” by providing more protected and prioritised right of way from other road traffic (Yarra Trams, 2010).

Tram Lane Configurations

The types of tram lane priority measures vary for different cities around the world, but their differences lie essentially in the amount of road space for trams and the types of separation provided for trams. At the highest level, trams are given grade-separated or physically segregated right-of-way (ROW); classified as “Category B type ROW” for trams by Vuchic (2007) and generally known as “tramways.” Tramways are mostly available in European, American, and Australian cities, and give trams the speed, safety, and time advantage necessary to compete effectively with the automobile. At a lower level of tram lane priority, tram lanes are designed for exclusive use by trams, either for the entire day (full-time tram lane) or for a specific time of the day (peak-hour tram only lanes/part-time tram lanes). These lanes have demarcation lines beside the tracks and overhead signs. There is no physical separation for these types of tram lanes. This is classified as “Category C type ROW” for trams (Vuchic, 2007) and often known as “full-time” and “part-time” tram lanes. These tram lanes are mostly available on Australia and North American tram/streetcar networks. A recent study by Naznin et al. (2018) investigated tram drivers’ perception of road safety for different tram lane configurations in Melbourne. The study found strong support from tram drivers for the raised tramways followed by the raised yellow strips beside tram tracks.

Tram Lanes and Road Rules

Tramways

A tramway is a part of a road with tram tracks that is between an overhead tramway sign and an end tramway sign as shown in Fig. 1A. Tramways are usually designed by raised tram tracks, raised dividing strips or double yellow lines beside the tram tracks. Fig. 1B shows an example of raised tram tracks and Fig. 1C presents a section of tramways with raised plastic yellow dividing strips beside tram tracks in Melbourne.

A driver (except the driver of a tram, tram recovery vehicle, or public bus) is not allowed to drive on a tramway and even not permitted to drive over raised dividing strips or double yellow lines except it is necessary to avoid an obstruction (VicRoads, 2019).

Figure 1 Tramway configurations. (A) Overhead Tram Only Lane sign for tram ways. (B) Raised tram track. (C) Tram way separated by raised yellow strip.

Figure 2 Tram lane configurations.

Figure 3 Mixed traffic tram operation. Source: <https://images.app.goo.gl/y7abBirm68CJJ2s1A>.

Tram Lanes

Tram lanes are divided from traffic by a single yellow line beside the tram tracks. They can be full-time (24-h) or part-time. Overhead signs indicate the hours of operation (Fig. 2A). Fig. 2B illustrates an example of tram lane section in Melbourne with overhead tram lane operation sign and a single yellow line beside tram track. A driver (except the driver of a tram, tram recovery vehicle or public bus) may only drive in a tram lane for up to 50 m to turn right, or to avoid an obstacle, providing that an approaching tram has not been delayed. The driver must have to move out of the path of the tram as soon as the driver can do so safely.

Mixed Traffic Tram Lane

On mixed traffic tram lanes, trams share the road with general road traffic and trams do not have any priority on tram lanes over general traffic and pedestrians (Fig. 3).

Railway Crossing

Railway crossings are an integral part of transport networks in many countries. In Australia, there are more than 23,500 railway level crossings (Larue et al., 2018a). The United States has approximately 212,000 railway crossings (Soleimani et al., 2019). However, their existence causes a severe risk to the safety of road users. Statistics show that there are around 100 incidents at railway level crossings every year in Australia (Australian Transport Council, 2010). In Sweden between 2008 and 2012, 59 accidents occurred at road-rail crossings (Jonsson et al., 2019). Although the number of crashes is relatively low, the impacts of these crashes on lives, both fatalities and serious injuries, and financial costs have the potential to be catastrophic. In Australia, these accidents result in an average of 37 deaths annually and more than \$100 million in losses (Australian Transport Council, 2010). Thus, over the past few decades, countries have made great efforts to improve railway crossing safety.

Types of Traffic Control

There are two types of traffic control systems that are used at operational railway crossings in worldwide. They are passive and active railway crossings (see Fig. 1).

Passive railway crossings have no active warning devices. Only signs and line markings are placed to attract road users' attention and warn them that there is a railway crossing ahead. They need to decide when it is safe to cross by estimating the arrival time and speed of a train at the railway crossing. The safety of road users entirely relies on their awareness of warning signs and their judgment. Passive railway crossings are normally used in rural areas, where the speed of trains is relatively faster than that in urban areas.

Active railway crossings provide a warning through active devices. These devices include flashing lights, alarms, and boom gates. They can react to the presence of an approaching train, which is different from the passive control. This kind of control system is mainly used on high-traffic volume roads.

The proportion of these two traffic control systems is different in various countries. In Australia, 79% of railway level crossings are passive (Australian Rail Track Corporation, 2016). The majority of them use either a "Stop" or "Give Way" sign, so road users are expected to check the presence of an approaching train. The remaining 21% of railway level crossings are active. They usually used flashing lights or boom gates to alert road users when a train is coming. In Finland, there were 22% active railway level crossings (Laapotti, 2016). Most of them were equipped with both flashing lights and bells. Also, all active devices were controlled automatically without the intervention of railway staffs in Finland, which is different from Britain (Evans and Hughes, 2019). They have manual control railway crossings. However, in some European countries, the proportion of passive railway crossings is less than the active one. For example, 15% of railway crossings in Belgium were passive in 2011, 30% in France, and 36% in Germany (Laapotti, 2016).

Currently, with the development of intelligent transport systems (ITS), some innovative technologies are emerging to complement existing traffic control systems at railway crossings. They include vehicle-to-vehicle (V2V) and vehicle-to-infrastructure (V2I) communication technologies. By adopting these technologies, the information from trains can transmit to road vehicles and warning infrastructure at railway crossings. The vehicles equipped with appropriate devices such as Global Positioning System (GPS) navigation systems and dedicated short-range radio communication systems will receive advanced warnings in time to avoid collisions. Compared with traditional control systems, they could significantly improve the safety of road users at railway crossings.

Figure 1 (A) A passive railway crossing; and (B) An active railway crossing. Source: NSW Government (2017)

Safety

Based on the Australian Transport Safety Bureau (ATSB) report, there were 601 collisions between road vehicles and trains at railway crossings between 2002 and 2012 (Australian Transport Safety Bureau, 2012). Safety at railway crossings has become a significant concern to the Australia Transport Safety Bureau. They investigated some railway level crossing incidents, and found these incidents have some similar characteristics (1) fatal level crossing incidents most often occurred in daylight on a dry road; (2) nearly half of the fatal incidents are attributed to unintended road user error; (3) fatal incidents frequently occurred at active railway crossings; (4) most of the fatalities at railway level crossing are to pedestrians. In addition, they also pointed out that although collisions normally occur between light vehicles and trains, the collisions between heavy vehicles and trains have a growing trend recently. These collisions will cause severe consequences.

Over the past decades, a number of studies analyzed the factors influencing the safety of railway crossings. Some studies found that passive railway crossings pose a significant safety risk. The reason is that at a passive railway crossing, road users are required to decide when it is safe to cross. However, there is usually no information provided for road users to make a decision. The errors of human judgment constitute a significant factor associated with crashes at passive railway crossings. For example, although some drivers recognize that there is a railway crossing, it is hard for them to notice warning signs. It leads to that they are not sure whether they need to stop at a railway crossing or not, which might increase the possibility for rear-end collisions. Also, drivers have difficulty in estimating the speed of an approaching train. Larue et al. (2018a) conducted a field-based experiment to test drivers' ability to estimate train speeds. The results showed that most participants underestimated the train speed by 30%. It indicated that they might be less likely to detect their potential risks of traversing a railway crossing. They might cross it in a limited safe space. It will increase the potential for near misses.

Recently, some passive crossings have upgraded to active crossings in many countries to improve safety. Although active railway crossings reduce the errors in judgment, there is also a risk of collisions because other forms of behavior errors happen at this kind of crossings. For example, drivers and pedestrians might not comply with active railway crossing rules. Some active control systems are designed based on the principle of ensuring the safety of road users to the greatest extent possible. It means that when a train is coming, the railway crossing will be closed for a long time. Some road users are reluctant to wait a long time. Thus, they attempted to traverse a railway crossing when the boom gates were down because their experience told them that the closing time of railway crossings would be extended to ensure safety. Statistics show that these impatient behaviors often occur at a congested level crossing (Larue et al., 2018b). Also, drivers with sensation-seeking tendencies are more likely to take such action. Larue et al. (2020) further studied the relationship between these risk behaviors and waiting times. They found that waiting time less than three minutes can effectively reduce the likelihood of risky behavior. In addition, road users, especially pedestrians, deliberately choose to ignore the flashlights at railway crossings to save time, though these controllers are visible. Most incidents happened to those people who were very familiar with railway crossings and violated the active warning systems. Moreover, Larue et al. (2018b) pointed out that if a pedestrian disregards the flashing lights, other pedestrians are more likely to follow. It will significantly increase risks. Note that unlike other road crashes, crashes at railway crossings are more likely to be attributed to unintentional errors caused by road user behaviors, and less likely to be affected by fatigue, alcohol, or drugs (Australian Transport Safety Bureau, 2008).

In addition to road user-related factors, there are other environment-related factors associated with crashes at railway crossings. Some studies found that sighting distance is highly related to crashes between trains and road vehicles at crossings. The reason is that short sighting distances do not provide sufficient time and space for road users to make a decision. Also, the speed limit of the road at passive crossings most often was higher than at active crossings. It results in that the fatal incidents often took place at the passive crossing where the speed limit is high. A lower speed limit provides a sufficient time for road users to pay attention to whether a danger ahead exists. Besides, the road gradient also affects safety at crossings. Crashes are more likely to occur on uphill or downhill

roads. It is difficult for drivers to make a complete stop when vehicles go uphill or downhill to railway crossings compared with flat roads.

In order to reduce the risks at railway crossings, much effort has been devoted to developing accident prediction models. Earlier studies preferred to apply generalized linear models to predict the likelihood of crashes at railway crossings. These models are suitable for discrete crash data, and they are a powerful tool to examine the relationship between road accidents and explanatory variables (Zheng et al., 2016). However, a potential limitation of these models is that the correlation between variables needs to be predetermined. If there is no relationship between variables, the estimation model might lead to erroneous results. In recent years, data mining, as a new technique, has demonstrated great potential for exploring large data sets. Because this technique does not lie on assumptions, it has been adopted by experts to estimate crashes. However, limited studies used them to predict accident rates at railway crossings. Within these studies, decision tree models are the most commonly used data mining techniques because of its ease of use and comprehensiveness (Zheng et al., 2019). More recently, with the rapid development of deep learning, it might provide a new tool for examining the factors influencing safety at railway crossings and improving the accuracy of prediction models.

Moreover, analyzing real field data is the best way to understand road user behaviors at railway crossings. However, the number of collisions between trains and vehicles is low. Thus, there is not enough field data to study. Currently, the simulation-based method is a good alternative for generating a large amount of reliable data to assess the safety of different control systems at railway crossings. Kim et al. (2015) used this method to assess the influence of ITS devices on driving behavior. The results show that driver behavior is more likely to be influenced by passive crossings with ITS intervention than by active crossings.

Design

Railway crossings pose a significant safety risk to road users. Based on the above review of factors contributing to crashes at crossings, the following elements need to be vigorously considered before undertaking the design of a railway crossing.

The level crossing surface should be in good condition with no potential to cause a hazard to road users. Also, the selection of crossing surface type shall fully consider the road vehicle type, volume, and track configuration to make road vehicles smoothly traverse tracks (Australian Rail Track Corporation, 2016). The crossings should be situated on the flat ground as much as possible (Laapotti, 2016). It allows drivers to stop more easily before crossing and have sufficient time to make a decision.

Concerning the design of passive railway crossings, sight distance is the most critical element that needs to be considered. Its design can be based on the road traffic mix. In general, the sight distance requirements for heavy vehicles are more stringent than those for light vehicles. Also, trees that might restrict visibility should be removed or trimmed. Buildings are forbidden to be established in the line of sight area at a railway crossing because they would influence existing visibility. Moreover, operators need to enhance the conspicuity of warning signs (Yeh and Multer, 2007). The signs can be illuminated or reflectorized to remind road users that they are approaching a railway crossing. Lowering the height of warning signs also can enhance its conspicuity. In addition, the speed at a passive crossing should be limited to a specific range. A higher speed limit might result in that road users are not aware of the danger and deliberately disregard warning signs (Laapotti, 2016). It would escalate risks at railway crossings. Furthermore, operators need to develop in-vehicle warning systems further. Combining them with passive countermeasures can provide more information for road users.

Waiting time is a critical factor that needs to be considered when designing an active crossing. Reducing waiting time would improve compliance (Larue et al., 2020). Also, the reliability of active warning systems shall be improved. It means that false alarms and failures of warning signals should be avoided. Besides, lowering and extending gate arms might reduce road user risk behaviors. Moreover, flashing lights can be upgraded to traffic signals. In comparison to flashing light, road users have familiarity with this type of signal; thus, they will be more likely to comply with traffic signals (Lenne et al., 2011).

Regarding the design of pedestrian crossings, in addition to the above aspects, particular users need to be considered. The crossing should make sure that the wheelchair users and children can access the surrounding infrastructures, such as public transport stations (De Gruyter and Currie, 2016). Also, local weather patterns such as fog shall be considered. It might influence pedestrians' line of sight. Moreover, if pedestrian crossings have high pedestrian usage rates, the lowest speed limit of rail traffic should be used, or grade separation shall be seriously considered. Besides, cyclists are sensitive to the traversing angle at skewed railway crossings (Ling et al., 2017). A higher angle can dramatically reduce crashes.

In July 2019, Federal Highway Administration published the 3rd edition of the Highway-Rail Crossing Handbook, which provides best practices as well as adopted standards relative to highway-rail grade crossings. The handbook contains the designs of geometry, illumination, crossing surfaces, sight distance, markings, treatments, signals, warnings, gates, access, and pedestrian treatments (Brent and Chelsey, 2019).

Policy

To reduce the likelihood of crashes at railway crossings, some strategies were proposed and implemented in various countries. These strategies can be summarized as four key areas, including education and enforcement, technology, knowledge management, and risk management.

Education and Enforcement

Educational measures are used to change road user behavior. Safety education campaigns conducted in some countries, which can increase the safety awareness of road users and improve community understanding of the risks. The Australian state government, New South Wales (NSW), conducted a campaign called “Don’t rush to the other side” from 2016 to 2017. The campaign was broadcasted through television, outdoor billboards and petrol pumps, radio, digital, and social media. The campaign was very successful for particularly the drivers of the light vehicles claiming that their behaviors and attitudes toward the railway crossings were changed (NSW Government, 2017).

Also, local law enforcement can remind road users of the penalties for violating the road rules and deter risk behaviors. Police are responsible for the detection of violations at level crossings in most countries. This should be shifted to technology since the police cannot provide sufficient enforcement coverage where technology such as cameras, sensors, and emerging detectors provide a wide-scale permanent and consistent detection coverage. The technology might detect road users’ plate numbers, face, behavior, and whether they violate the rules (Economic Commission for Europe, 2017).

Technology

New engineering and technological solutions are adopted to improve safety and efficiency at railway crossings. Also, research efforts should continue to develop new types of crossing controls and warning infrastructure.

Very recently, a vehicular communication system has been emerging in railway crossings too. The specific types of communication include V2I (vehicle-to-infrastructure), V2V (vehicle-to-vehicle), and V2X (vehicle-to-everything). Connected vehicle-based warning systems warn road users to stop for crossing to mitigate the risk of grade-crossing collisions. The warning is delivered by visual and/or audio alerts and the display of the estimated waiting time (Wang et al., 2019).

Knowledge Management

Data is vital to support decision-making and accident data of crossings is relatively sparse. It is desirable to create a national database, including road traffic data at railway crossings, to reduce data gaps. Each jurisdiction can access these data and analyze them to understand road user behavior better and examine characteristics surrounding incidents.

The decision making process can be driven by dynamic and static datasets from different sources, including service failure data, signal data, ballast history, grinding history, remedial action history, traffic data, inspection data, as well as curve and grade data (Ghofrani et al., 2018). The data sources include acoustic bearing detectors, hotbox detector (HBD) temperature trending, hot/cold wheel detectors, truck performance detectors, hunting detectors, wheel impact load detectors (WILD), cracked axle detectors, cracked wheel detector, and machine vision (Wang et al., 2018, Stratman et al., 2007, Li et al., 2014).

NSW collected traffic controls, level crossing characteristics, and other related risks on all public level crossings. Two streams of data collection projects store ALCAM (Australian Level Crossing Assessment Model) field assessments at 212 road and pedestrian level crossings on the ARTC (Australian Rail Track Corporation) network and road traffic data collection (including type, volume, and speed of vehicles traversing a level crossing) at 315 level crossings in NSW (NSW Government, 2017).

Risk Management

Utilizing incident data and innovative modeling techniques is to develop an effective risk assessment model. Based on these models, estimating marginal accident costs is essential for operators to make an investment decision. Also, operators can use simulation methods such as driving simulator to compare different crossing controls and assess the risks before and after taking counter-measures. In addition, recent years witness countries implemented level crossing removal and grade separation programs to eliminate collision risks. It is necessary to develop a model to determine the suitability of these programs.

The Dutch Ministry released the 2016 framework policy after several revisions in 1999, 2004, and 2010. Since the safety performance in the Netherlands was satisfied in 2016, the Dutch level crossing policy changed a direction from safety performance indicators to risk factors (Dutch Safety Board, 2018).

The risk management framework in Victoria, Australia, was improved in 2010 by, in partnership with the road and rail managers who are able to provide knowledge and perspectives in level crossing safety and develop a comprehensive plan to manage the strategy (Victorian Auditor-General, 2010). Incorporating rail managers were critical since they are liable to assess level crossing safety and accredited as capable of managing the risks.

General Introduction

A pedestrian crossing (crosswalk) is an area designed specifically for pedestrians to cross a road that is being used by vehicular traffic. The core function of these facilities is to provide safe crossing opportunities for pedestrians with fewer delays. Pedestrian crossings are set in locations where they are clearly visible to drivers, and where pedestrians can cross the road most safely across vehicle traffic flow. Pedestrian crossings are a critical part of walkway networks, whose performance significantly affects the accessibility and walkability of pedestrian networks.

Marked pedestrian crossings can be seen at intersections and on busy roads, where crossing without them would be unsafe because of the large volume of vehicles, road width, and high speeds. Furthermore, pedestrian crossings are usually installed in areas that have considerable demand of crossing pedestrians, such as shopping areas, business districts, and near schools or hospitals where vulnerable road users regularly cross.

If vehicle demand is high, pedestrian crossings (especially with traffic signal control) may increase vehicle delay. Some advanced signal control methods enable delay minimization using pedestrian detection systems. Some structural devices have functions to minimize pedestrian exposure time to possible conflict with vehicles. This article introduces the components of pedestrian crossings and different control methods for improving efficiency and safety.

Classification of Pedestrian Crossings

Pedestrian crossings are divided into two types: unsignalized and signalized. The former is installed at locations with low demand of vehicles and pedestrians, whereas the latter are installed at locations with a relatively higher demand. Unsignalized crossings can be further classified according to the existence of pavement markings and types of facilities. Unsignalized crosswalks with zebra-shaped pavement markings are called Zebra Crossings, in which pedestrians have full priority to cross the road. Crossings without markings do not prioritize pedestrians, but instead include refuge islands, humps, and other physical facilities to ensure the visibility of crossing locations for safety reasons. In order to provide pedestrians with safe crossing opportunities, in cases of both priority settings, it is necessary to consider the followings to provide safe crossing opportunities for pedestrians; (1) both pedestrians and drivers can easily recognize each other and avoid conflicts at crossings, and (2) the crossing time of pedestrians (pedestrian exposure time to vehicle flow) is minimized.

Signalized crossings are classified by their control methods and pedestrian detection functions. In Pelican crossings mainly used in the United Kingdom, fixed green and flashing amber/green periods are given to pedestrians according to the demand requested by

Figure 1 Zebra crossing with hump and refuge island.

the push-button. Hawk crossings used in the United States or Canada have similar functions as Pelican crossings. In addition to push-buttons, Puffin crossings detect pedestrians at crossings and adjust the time such that pedestrians can safely complete crossing before the subsequent green for vehicles starts. Toucan crossings are designated for both pedestrians and cyclists, and Pegasus crossings are for horse-riders.

Recently, several guidelines or tools are published to assist practitioners to select proper types of pedestrian facilities taking into account the traffic and geometry conditions at crossings. [Federal Highway Administration \(2018\)](#) provides a guidance to choose geometric layout of unsignalized crossings from safety viewpoint. [Austroads \(2015\)](#) developed a tool to support the selection of crossing types by the combination of the feasibility check and the cost-benefit analysis, considering delay, safety, and walkability index perceived by crossing pedestrians as benefits obtained by construction of crossing.

Unsignalized Crossing

Zebra Crossing

Zebra crossings are crossings with zebra-shaped pavement markings ([Fig. 1](#)), where pedestrians always have the right of way to cross over vehicles. In the UK and some other countries, poles with a flashing globe lamp must be deployed to ensure visibility of the crossings as in [Fig. 1](#). Zebra crossings are widely used not only at midblock crossings but also at unsignalized intersections. [Fig. 2](#) is an example of an unsignalized intersection in Switzerland, where yellow-colored markings are applied.

As described in the note by Department for Transport, The National Assembly of Wales, The Scottish Executive and The Department for Regional Development ([Department for Transport, 1995a,b](#)), pedestrian delays are minimal because they have priority to cross at Zebra crossings. However, if vehicle demand is high, pedestrians may feel threatened to proceed as there would only be small gaps between vehicle arrivals, and vehicles may not yield to pedestrians. This may increase pedestrian delay. In

Figure 2 Zebra crossings with refuge islands at an unsignalized intersection.

Figure 3 Refuge island without zebra-shaped pavement markings.

contrast, if pedestrian demand is too high, vehicles have limited opportunity to pass the crossing and their delays increase significantly. Therefore, it is not reasonable to install Zebra crossings at locations with high pedestrian demand conditions.

If vehicle approach speeds are high, Zebra crossings are not suitable because pedestrians can be exposed to a higher risk of more serious injury. In such cases, installation of signalized crossings or physical facilities to reduce the speed of approaching vehicles can be considered.

Other Unsignalized Crossing Facilities

If the road width is quite wide and pedestrians have to cross the road at once without stopping, the pedestrian crossing time is increased, and the possibility of crossing pedestrians meeting oncoming traffic is also increased. In order to avoid possible risks, several physical facilities can be installed at pedestrian crossings. The facilities also serve to improve the visibility of the crossing to drivers such that they will be aware of crossing pedestrians on the road.

Raised medians or refuge islands are crossing facilities installed between vehicle lanes. These facilities enable pedestrians to cross the road with several stops. For two-way streets, pedestrians usually need to check for vehicles coming from both directions. If raised medians are installed, pedestrians need to check for vehicles from only one direction at once. In this manner, pedestrians can concentrate on vehicle arrivals from specific lanes, thus easing their decision for an appropriate time to cross. **Fig. 3** is an example of a refuge island, where there are no zebra markings. Pedestrians using the island are not guaranteed to have priority but they are required to search for a gap between vehicle arrivals. This type of crossing is installed at locations with less vehicle and pedestrian demands. For further discussions, refer to the chapter of "Stage Crossing."

Narrowing vehicle lanes also works effectively to reduce the crossing distance. For example, in a road section with high parking demand, outer most lanes can be utilized as parking spaces and these lanes can be removed at the location of pedestrian crossing. **Fig. 4** shows an example with the vehicle lane narrowed at a Zebra crossing. This strategy also improves the visibility of the crossing such that drivers can stop the vehicle at the crossing.

Humps are another type of physical facility, which reduce vehicle speed by their vertical alignment. Sometimes, humps are installed at zebra-marked areas of Zebra crossings. As sidewalks are usually slightly elevated than vehicle lanes, crossings with humps can be designed such that there is no difference in the level of the crossings and sidewalks. This barrier-free treatment is advantageous for disabled pedestrians.

Signalized Crossing

Crossing and Clearance Times for Pedestrians

Generally, pedestrian crossing time consists of a discharge time and a clearance time as summarized by [Iryo-Asano and Alhajyaseen \(2014\)](#). The discharge time is the time necessary for pedestrians waited for the green to leave the curb for crossing. Pedestrians need to have some time to start crossing by responding to the green traffic light indication. If there is high pedestrian demand, additional times need to be provided so that all pedestrians waiting in the queue are able to leave the curb.

The clearance time is the time that pedestrians can have sufficient time or crossing before the subsequent vehicle green phase. Usually the clearance time is provided so that pedestrian can cross the entire crosswalk length. In order to calculate the clearance time, we have to assume pedestrian walking speed. However, pedestrian speeds vary significantly. To ensure the safety, slow walking pedestrians such as elderly and disabled should be considered in setting the walking speed for the estimation of the needed clearance interval. This also means that in many cases the given clearance times are too long for most of the pedestrians and there will be the time that is unused by anybody. This will decrease the efficiency of the traffic signal control. The control systems introduced below (Pelican, Puffin, and Hawk crossings) have advanced functions to remove such unused times.

Figure 4 Zebra crossing (narrowing the road).

Figure 5 Pelican crossing. (A) Push-button of Pelican crossing, (B) Location of traffic lights and push-buttons.

Pelican Crossing (PEdestrian Light CONTROLLED crossings)

Pelican (previously Pelicon) crossings are equipped with push-buttons at each edge of the crossing as well as pedestrian signal indicators at the far-side of the crossing (Fig. 5). Pedestrians wishing to cross the road push the button, after which the green lights for vehicles turn into amber followed by red, and then the steady green (green man) is indicated for pedestrians to cross. Pedestrians are allowed to cross only when this steady green is indicated. After a few seconds, pedestrian traffic lights start flashing. At the same time (often a few seconds after the onset of pedestrian flashing green), flashing amber is indicated to vehicles. During this period, pedestrians on the crossing can keep crossing with priority while pedestrians outside of the crossing should not start to cross. If there are no pedestrians on the crossing during flashing green/amber, vehicles are permitted to pass through the crossing. Pelican crossings do not include any sensors for actively detecting crossing pedestrians, and the durations of the steady and flashing green are fixed. Pelican crossings are installed in the United Kingdom and several other countries.

Pelican crossings can reduce unnecessary vehicle delay because vehicles are allowed to pass through the crossing during the flashing amber period after all pedestrians complete crossing. Meanwhile, it may not be able to provide sufficient crossing time to slowly moving pedestrians because there are no sensors to detecting the existence of pedestrians on the crossing.

Under light vehicle traffic demand, a scenario may also arise where pedestrians who pressed the button may cross the road before traffic lights turn to green. In this case, Pelican crossings will provide unnecessary pedestrian green times that are not used by any pedestrians.

Puffin Crossing (PEdestrian User Friendly INtelligent crossings)

Puffin crossings have pedestrian traffic lights located on the same side of the road for pedestrians, diagonal to the road edge, while most of other types of pedestrian traffic lights are placed at the far (opposite) side of the crossing. This means that pedestrians at

Figure 6 Facilities of Puffin crossing.

Figure 7 Push-buttons and traffic lights of Puffin and Toucan crossings. (A) Puffin crossing, (B) Toucan crossing.

Puffin crossings cannot see the traffic lights when they are crossing (as in Fig. 6). This will give the chance for pedestrians to monitor the traffic while they are waiting for the pedestrian green signal indication to cross the street.

Most Puffin crossings comprise sensors installed on the top of traffic lights, and the sensors are sometimes embedded in the ground, especially in the waiting area. These sensors can detect the presence of pedestrians waiting to cross. This will allow canceling of the crossing demand and skipping to provide the pedestrian green when there are no such pedestrians. Some sensors use infrared, microwave, and other types of detection techniques to extend the crossing time if there are pedestrians still crossing the road. Vehicle drivers waiting at puffin crossings are not permitted to pass until all pedestrians have finished crossing the road.

Puffin crossings do not provide flashing green/amber indications. Pedestrian steady green immediately turns into steady red. Pedestrians can start crossing during the steady green period. After the signal turns into red, only pedestrians on the crossing can continue to cross. Red lights for vehicles turn to green after sufficient clearance time that allows pedestrians on the road to complete crossing. This clearance time is adjusted according to the detection of pedestrians by sensors. This allows the system to accommodate slow pedestrians such as elderly and people with disabilities.

Puffin crossings can overcome some issues of Pelican crossings by utilizing pedestrian detectors. The crossing time is automatically extended according to the existence of pedestrians. Additionally, Puffin crossings cancel the call if there are no more pedestrians on the sidewalks. However, due to the equipment of sensors, maintenance, and construction costs are higher than those of other control systems.

Puffin crossings are used in the United Kingdom and other countries. As a similar type of crossing, Toucan crossings are also used in the United Kingdom. Toucan crossings have similar traffic signal heads as Puffin crossings, but bicycle signs are indicated next to pedestrian signs (Fig. 7).

Hawk Crossing (High intensity Activated crossWalk)

Hawk crossings, also known as Pedestrian Hybrid Beacon (PHB), are another type of crossing used in the United States and Canada. The system is similar to the Pelican crossing. The vehicle traffic signal is dark until the crossing is activated by pedestrians (usually by push-buttons). Once activated, the vehicle signal starts flashing yellow lights to warn drivers of pedestrian presence. Then, the flashing yellow changes to steady yellow and then steady red, instructing drivers to stop. In the meantime, "WALK" signs are given to pedestrians for crossing. After "WALK" signs, the pedestrian signal turns to flashing "DON'T WALK" signs and the vehicle signal turns to flashing red. The flashing red signal has the same meaning as the flashing green/amber in Pelican crossing, during which vehicles can proceed if there are no more pedestrians crossing. Finally, the vehicle signal turns back to dark and the pedestrian signal turns to steady red "DON'T WALK" until any next activation by pedestrians.

Crossings at Signalized Intersections

Pedestrian–Vehicle Separation Controls

At signalized intersections, the pedestrian green signal is often provided simultaneously with parallel vehicle green, permitting vehicles to turn across the crossings. Although vehicles have to yield to pedestrians, there is a potential for hazardous conflict between turning vehicles and pedestrians when drivers do not recognize pedestrians.

Table 1 Pedestrian–vehicle separation controls.

Control types	Examples of phasing plan (ϕ_i : phase number i)
1. Dedicated pedestrian phase	Dedicated pedestrian phase is provided. During this phase, vehicles cannot enter the intersection and pedestrian can cross any crosswalks. Scramble crossing: diagonal crossings are allowed   
2. Turning vehicle separation	Pedestrian phase and conflicting turning vehicle phase are separately provided. (Note: dedicated lanes for every movement are required.)   
3. Leading pedestrian interval	Pedestrian phase starts a few seconds earlier than conflicting turning vehicle phase. 

As a pedestrian-oriented control type, pedestrian–vehicle separation controls have been gaining attention recently. Examples of pedestrian–vehicle separation controls are shown in [Table 1](#). They are installed when capacity or safety problems are expected because of conflicts between pedestrians and turning vehicles. Dedicated pedestrian phases are additional phases where only pedestrians are allowed enter the intersections. Scramble crossings, which even allow diagonal crossing at intersections, are also classified into this type. Turning vehicle separation is a phasing plan that separately provides the right of way to pedestrians and conflicting turning vehicles. Various patterns of phasing can be considered in this type, but two typical examples are given in [Table 1](#). It should be noted that dedicated vehicle lanes are required for all directions to apply these phasing plans (no shared lanes) because all directions have a right of way at different timings.

Leading Pedestrian Interval (LPI) is a phasing plan in which the pedestrian green starts a few seconds prior to the vehicle green. In ordinary control with simultaneous phasing, there is a high probability of conflict between pedestrians and turning vehicles at the beginning of the green indications because both of them start to discharge at the same time. In LPI, platoons of queued pedestrians can start crossing earlier and the probability of conflict decreases. Even if pedestrians are still crossing at the onset of vehicle green, their visibility from drivers are high enough and they can cross safely.

Stage crossings with refuge islands are also utilized to improve the efficiency and/or safety of intersections. See the cross references for more details.

Scramble Crossings

A scramble crossing (also called a Barnes Dance) is a type of pedestrian–vehicle separation phase that provides an exclusive pedestrian phase for all pedestrians. In this phase, no vehicle can enter the intersection. All pedestrians are allowed to cross towards any direction, even diagonal paths in the intersection. This phasing plan can reduce conflicts between pedestrians and vehicles.

Scramble crossings are often installed in central business districts with high pedestrian demand. In these districts, scramble crossings are also regarded as landmarks or symbols of areas for walking places. The scramble crossing located in front of Shibuya station in Tokyo, Japan ([Fig. 8](#)), enables more than 1000 pedestrians to cross at once. Another use of scramble crossing is to achieve safer crossing for children. [Fig. 9](#) shows an example of scramble crossings located in front of an elementary school.

Although scramble crossings can fully separate the right of ways between pedestrians and vehicles, it should be noted that the pedestrian green time in scramble crossings is considered as lost time for vehicles. This period completely prohibits vehicle flow, which deteriorates the efficiency of vehicle traffic. In general, the cycle length (duration to complete a sequence of signal phasing) with scramble crossing tends to be longer than that of an ordinary phasing plan. Furthermore, with higher vehicle demand, the cycle length is also increased to ensure capacity. Longer cycle lengths correspond to longer vehicle delay, and there is a possibility that drivers in hurry may rush into the intersection just before the traffic signal turns red. Pedestrians may also get irritated waiting for the long cycle and take illegal crossings. Therefore, to install scramble crossings, vehicle demand should be carefully examined such that cycle length is kept within an acceptable range.

Additional Considerations

Consideration for Disabled People

Crossings with push-buttons, such as Pelican or Puffin crossings, support blind/visually impaired pedestrians by providing non-visual signs that notify pedestrians that it is safe to cross. There are various types of equipment, such as beepers, vibrating buttons, and rotating knobs installed under the wait box.

Figure 8 Scramble crossing in a business district (Shibuya, Japan).

Figure 9 Scramble crossing near a school (Nagoya, Japan).

Figure 10 Example of countdown pedestrian signal head. Source: From *International Association of Traffic and Safety Sciences (IATSS) (2007)*.

At signalized intersections in Japan, two different types of sounds or melodies are used at one intersection to announce pedestrian green. The two types of sounds correspond to different phases of the intersection such that visually impaired pedestrians can distinguish the green signal.

Countdown Signals

To improve pedestrian safety and comfort, countdown pedestrian signals are widely utilized. There are several types of countdown signals worldwide, and the two most common types display the remaining time either in seconds or dots. The former type is typically used, for example, in the United States, with the remaining seconds being shown along with flashing “DON’T WALK” signs. An example of the latter type is that used in Japan, as shown in **Fig. 10**. At the beginning of the pedestrian green, all dotted lights are displayed as in the left hand side of **Fig. 9**. The dots disappear one by one as time proceeds, and all dots disappear when the pedestrian flashing green starts. Similarly, countdown red dots are displayed during the red time.

Introduction

The active mobility, particularly walking and cycling, has been heavily promoted as a sustainable alternative to motorized vehicles. The rise in the participation of active transportation modes in the modal split has been pointed out as an economically viable way to improve the overall mobility in the cities. However, its benefits can go far beyond the reduction of traffic congestion levels, optimization of urban infrastructure use, and, in the case of cycling, the reduction of total travel time and cost. It also may comprises lowering the noise, pollutants, and greenhouse gases (GHG) emissions that are generated by transportation activity. More than this, it may help to improve public health as well as to reduce the associated costs of it, as it increases the individuals’ physical activity levels, which ultimately contributes to enhancing the population quality of life and lower mortality rates. Moreover, the increase in the active mode share can contribute to decrease the number and severity of traffic accidents, reduce crime rates, facilitate social interaction and networking, positively affect housing prices and the local economy in general. All these factors make cycling an excellent choice for cities that aim to be livable and sustainable (Bieliński and Ważna, 2019; DeMaio, 2009; Ellison and Greaves, 2011; Granville et al., 2001; Jacobsen, 2015; Kabak et al., 2018; Liu et al., 2012; Ogilvie et al., 2004; Rojas and Wong, 2017; Schabus, 2020; Toronto, 2012; Zhang et al., 2015).

As a mode of transport, bicycles are a promising alternative to partially replace the use of private automobiles due to their flexibility and low cost, being a competitive option especially for travels under 5 km in urban areas (Buehler, 2012; Kumar et al., 2016; Li et al., 2013; Ma et al., 2018; Millward et al., 2013; Van Wee et al., 2006). Due to its numerous positive characteristics for the users and the city environment and considering all the negative impacts caused by the unrestricted use of private automotive vehicles in urban centers, cycling has emerged as an attractive option to urban transport being used both alone for short distances in daily commuting trips as well as integrated with public transportation creating a door-to-door network (Kumar et al., 2016). Thus, cycling has been globally promoted through the provision and improvement of cycling infrastructure and by the raising of population awareness on its individual and collective benefits. In this context, public bicycle schemes, also known by other names such as bike-sharing schemes, bike-sharing systems, public bicycle share, or public bike-sharing system, appeared in line with the principles of economic, social, and environmental sustainability.

The public bike-sharing systems (PBSS) comprise a scheme of self-service public bicycles and pedelecs that are shared, usually in urban areas, by individuals for a certain period with or without the payment of a rental fee. At present, there are three types of PBSS: the station-based bike system (SBBS), the free-floating bike system (FFBS), which is also referred to as the dockless bike system, and, recently, the hybrid bike-sharing system (HBSS), which combine the first two models.

The SBBS comprises bicycles that can be rented and returned after usage in any of the system’ docking stations. Whereas, the bicycles used in the FFBS can be rented and returned anywhere within the operating area, being necessary simply park and lock them using the mobile app. Finally, the HBSS gathers features of both schemes. It offers the possibility to track the nearest bicycle and unlock it using the app as well as to return it anywhere in the same way that users can do while using the FFBS. However, in this scheme, there are also stations from where the bicycles can be rented and where they can be returned to after usage just like in the SBBS (Albiński et al., 2018; Bieliński and Ważna, 2019; Caggiani et al., 2018; Pal and Zhang, 2017; Shen et al., 2018).

The Public Bike-sharing Systems: Then and Now

The first public bike-sharing system was launched in Amsterdam by a group of activists a few decades ago, in 1965, under the name of *Witte Fietsen* (White Bikes). The system counted with 50 unlocked white bicycles to be used anonymously and free of charge by

anyone who intended to, as part of a social/shared economy. Even though this experience was unsuccessful as the bicycles were stolen or damaged within days, it was later known as the 1st generation of the public bike system (Chardon, 2019; DeMaio, 2009; Kabak et al., 2018; Shen et al., 2018). After the failure of the White Bikes, other cities such as La Rochelle (France), in 1974; Cambridge (United Kingdom) in 1993, and Portland (USA), in 1994, also implemented public bike-sharing schemes with the characteristics of the 1st generation but only the La Rochelle systems had not faced a fast fade (Shaheen et al., 2010; Melo and Maia, 2013).

It was in the cities of Farsø and Grenå (Denmark) that, in 1991, a system emerged with characteristics that would later be recognized as belonging to the 2nd generation. Although another system was opened in the city of Næskov in the same country 2 years later, it was only in 1995 that a large-scale system was launched. This system, which was located in Copenhagen, Denmark, begun to operate in 1995 with 110 stations and 1100 bicycles. Unlike in the 1st generation, the systems of 2nd generation implemented stations from where the bicycles should be taken and returned upon a refundable deposit. As a coin was required as a deposit, the systems of this generation started to be referred to as "coin-based-systems". Due to the need to return the bicycle to a station to get the deposit back, the incidence of theft and vandalism decrease, however, it was still a problem as the user remained anonymous (DeMaio, 2009; Shaheen et al., 2010). Over the years many other cities implemented this type of system. The *Bycykler* in Sandnes (Norway), in 1996; the *City Bikes* in Helsinki (Finland) in 2000; the *Bycykel* in Aarhus (Denmark) in 2005; the *Yellow Bike Project* in Minneapolis and Saint Paul in 1996 and Austin in 1997; the *Red Bike* in Madison in 1995 and the *Freewheels* in Princeton in 1998, all in the USA, where some of the systems that operated using the 2nd generation model. Even overcoming some of the problems of the previous generation through the reduction of the stealing and vandalism the systems that used this operational scheme did not last as there were still problems due to the lack of control over the return and usage time (Melo and Maia, 2013).

The 3rd generation brought some innovations that helped to considerably lessen the occurrence of robbery and vandalism. The use of information communication technology (ICT) was the main improvement incorporated into the systems of this generation, which are usually referred to as "SmartBike" or "IT-based system". Instead of a coin, the bicycles of this generation were unlocked at the stations through the use of a personal card, which made the registration in advance mandatory, thus, ending anonymity. The first system with these characteristics received the name *Bikeabout* and appeared inside the campus of the Portsmouth University (England) in 1996. However, it was only in 1998, in Rennes (France), that systems with these features became available for general public under the name *Vélo à la carte* (later known as *Le vélo Star*). In contrast with the previous generations, this system was free of charge only for the first 30 min of use, being the exceeded time charged on the credit card indicated for the user during the registration (DeMaio, 2009; Melo and Maia, 2013; Shaheen et al., 2010). In Asia, the first system was opened in 1999. The Singaporean system received the name of *TownBike* (later renamed as *SmartBike*). No longer after, Japan launched the *Taito Bicycle Sharing Experiment* in 2002.

The 3rd generation was a success and made the PBSS internationally known. The bike-sharing scheme attracted even more attention when in 2005, 2007, and 2008 three new systems were launched in the cities of Lyon (*Vélo'v*), Paris (*Vélib'*), and La Rochelle (*Yélo*), respectively, incorporating new technological innovations. These three French systems were equipped with Global Positioning System (GPS) tracking. The use of GPS technology made it possible for the service providers to assess real time data about the bicycles' location as well as the status of the stations and information about the users (DeMaio, 2009; Melo and Maia, 2013). Due to these improvements, some authors even categorize these systems as part of a so-called 3rd generation plus (Assim Mohammed, 2017; Bieliński and Ważna, 2018). These innovations represented a significative advance for the systems' operation and management, which also contributed to raise users' satisfaction. Thereafter, the system spread rapidly across the world.

South Korea started their system *Nubija* in Changwon city in 2008. In the same year, China implemented the *HZ Bike* in Hangzhou city. Taiwan, then, introduced in the cities of Kaohsiung and Taipei the *C-Bike* and *YouBike* systems in 2009. The first American system was debuted in Washington (USA) in 2008 and received the name *SmartBikeDC* (later renamed as *Capital Bikeshare*) (Shaheen et al., 2010; Melo and Maia, 2013).

No longer after this, systems started to blowout in other continents. Auckland (New Zealand), in 2008, inaugurated the *NextBike*, Australia, in 2010, launched the *CityCycle* in Brisbane and the *Melbourne Bike Share*, in Melbourne. In Latin America, the *B'easy* was introduced in Santiago, Chile, in 2010; the *EcoBici* was presented in Mexico City, Mexico, in 2010; the *Mejor enBicici* (which became *EcoBici* later) was announced in Buenos Aires, Argentina, in 2010; the *EnCicla*, was created in Medellín, Colombia in 2011; the *UseBike*, was introduced in Sao Paulo, Brazil in 2008 and then replaced by the *Bike Sampa* in 2012; what also happened in Rio de Janeiro, Brazil, with the *PedalaRio*, which has started in 2008 and was substituted by the *BikeRio* in 2011 (Melo and Maia, 2013).

It was in Montreal (Canada) that, in 2009, the system, called *BIXI*, that was going to become the first system of the 4th generation appeared. The 4th generation of PBSS introduced some new features into the systems being the main one the use of smart cards. The use of smart cards enabled the implementation of a unified payment structure and provision of real time information, not only about bicycles and stations, but also on the integration with other transit modes. More than this, the improvements included technologies that facilitated the demand-responsive redistribution and the value-pricing to stimulate self-rebalancing. Ultimately, these advances gave to the users the chance to better plan their trips as they could easily access all the information through their mobile-phone and, at the same time, it increased the control of the operators over their systems.

Aside from these IT-based innovations, the 4th generation was responsible to reintroduce the FFBS operation, eliminating the need of stations. The use of smart lock mechanisms accessed by mobile-phone applications brought back the flexibility and convenience of the systems of the 1st generation and, at once, maintained some level of control over the bicycles and users, which previously would only be possible in systems with stations (Melo and Maia, 2013; Shaheen et al., 2010; Shaheen et al., 2013).

Figure 1 Number of countries with PBSS (1965–2020) and global fleet size variations. Source: Meddin et al. (2020), Earth Policy Institute (2013) and Ferreira et al. (2020).

Besides the before mentioned flexibility and convenience that the absence of docking stations represented, the new version of FFBS brought a number of other advantages in comparison with the SBSS. From the operators' point of view, the absence of stations and payment kiosks made the implementation cost lower. The GPS technology enabled real time management and reallocation. It also helped to reduce the occurrence of theft. From the users' viewpoint, the systems became much more attractive. If before the users had to find a station and would face the uncertainty regarding the availability of bicycles or of free docks to return their bicycles after use, now with the FFBS, parking became no longer an issue. The possibility of parking anywhere made the FFBS a perfect alternative for door-to-door travel (Pal and Zhang, 2017).

Due to all these benefits, the systems of FFBS type became very popular and experienced an explosive growth. In 2017, there were more than 24 million PBSS in the world being a huge parcel of them in China. Nevertheless, the rapid growth brought a lot of problems. The lack of government control led to a chaotic scenario. Littering, inappropriate parking and oversupply caused an increase in risk of accidents and a reduction of the capacity of the walkways and roads, which ultimately contributed to lower city's walk ability, lesser users' satisfaction and give a bad image to cycling (Bieliński and Ważna, 2018). In order to overcome these issues, many cities implemented regulations, which led to a better equilibrium between the demand and supply, thus causing a drop in the total number of shared bicycles, from more than 24 million in 2017 to less than 10 million in 2020 (as shown in Fig. 1).

Fig. 1 presents an overview of the historical growth in the numbers of PBBS. As can be seen, the number of countries with PBBS has been growing consistently over the years. The growth curve became sharper after the 3rd generation of bicycles were launched in 2005 doubling in 2009 when the 4th generation emerged. The rise in the number of countries with this kind of system has a direct connection with the development and popularization of technologies as smartphones and the Internet.

Recently, the 4th generation also incorporated electric-assisted bicycles and hybrid operation (HBSS), which consists of the combination of the characteristics of the two types of PBSS. *Norisbike* in Nürnberg or the *MVGRad* in Munich are examples of HBSS. In the systems of this type the users can still start and finish a ride anywhere through the mobile phone application, just as in the FFBS, however, the system also provides some stations. The main functions of the stations are (1) recharge the batteries of the electric-assisted bicycles and (2) guarantee more availability of bicycles in strategic locations such as close by transit stations making it easier for the users to find a bicycle (or a place to park it) in these locations (Albiński et al., 2018; Bieliński and Ważna, 2019).

Even though there is no unanimity on what a 5th generation may be like, the fact is that the PBSS are still in ascension. Globally, it is estimated that, by August 2020, there were 2018 PBSS in operation. These systems were located in 1583 cities in 85 different countries around the globe. They counted together with around 9.4 million selfservice public bicycles and pedelecs (electrically assisted bicycles). There were also 318 systems planned or under construction and 691 systems that were no longer operating or that were temporarily closed (Meddin et al., 2020). The spatial distribution of these systems around the globe can be seen in Fig. 2.

As can be seen in Fig. 2, most of the systems are located in Europe and Asia. Europe counts with 41.9% of the systems in the world. It represents 845 systems distributed in 749 cities of 40 different countries. Considering that there are 44 countries in Europe according to the United Nations (1999), one can see that 91% of the European countries have at least one PBBS. Asia, on the other hand, has the biggest portion of the systems (43.6% of total), however, unlike in Europe, in Asia, the systems are not evenly distributed over the territory. This continent has 48 countries but only 24 of them (50%) have PBSS, being the vast majority of them

Figure 2 Spatial distribution of the bike-sharing systems in the world. Source: *Meddin et al. (2020)*.

located in Eastern Asia. China alone has 709 systems, which represent almost 81% of all the systems of this continent. The Americas have 269 systems located in 15 different countries, which means that 43% of the countries of these continents have at least one system. The majority of these systems are located in Northern America (73%), specifically in the USA (176 systems). Africa and Oceania are the continents with the lowest number of systems. Despite having 54 countries, only four of them have PBSS. Oceania, on the other hand, has systems only in two of its 14 countries, however, it is interesting to notice that there are 19 systems in the only two densely populated countries and all the other countries that have no systems are small islands.

In brief, we can say that almost half of the countries in the world have at least one PBSS. It gives us the idea of how much this kind of scheme spread globally and gained relevance in a short period of time. As previously stated, the first PBSS was launched a little over five decades ago and since then, many systems have been created but many have also ended up failing. Hereupon, it is important to understand that the rise and fall of systems are an intrinsic part of the process of development of this type of system. Thus, even if there is not a formula for success, it is possible to learn from previous experiences in order to foresee possible issues that can be avoided and be aware of factors that may contribute to the success.

The “Success Factors” for Public Bike Sharing Systems

When we talk about “the success factors” for bike-sharing it is important to understand that these factors are not universal. There is not a formula of success that can be applied to any context and that can guarantee the success of the system. There are, though, some essential elements, such as the provision of infrastructure, that are, indeed, key factors for success (in fact, they are almost a precondition to make cycle possible) that must be taken into consideration during the planning process. The elements that will contribute to increasing the system’s chances of success will deeply depend of the purpose of the system and of the particular characteristics of the city where it is going to be implemented (*Chardon et al., 2017*). All these parameters as well as the system feasibility, its detailed design and its business and financial model will be defined during the planning process (*Gauthier, 2013*).

The purpose of the system refers to what was the main intention behind the system implementation. For instance, if the bike-sharing system was projected aiming to reduce pollutant emissions and traffic congestion in the city center, it can be considered successful by the local government even if its benefits are restricted to a specific part of the city or if the system is deficient in other aspects.

Besides the purpose of the system, the factors that can lead to its success are strongly related to the characteristics of the city where it is going to be implemented. If on the one hand, bike-sharing systems are considered a more affordable mode of transport, on the other hand, studies have shown that the systems do not necessarily promote social equity. More than this, depending on how it is designed it may highlight and deepen some preexisting class, gender, and race inequalities (Chardon et al., 2017; Ricci, 2015; Ursaki and Aultman-Hall, 2015). The same logic applies to health benefits. If it is undeniable that the physical activity promoted by cycling can contribute to enhancing the population quality of life and health, researches have concluded that in some contexts the benefits of cycling do not overcome the harm to health that the increased exposure to pollutants and to the risk of traffic accidents or even the reduction of physical activity levels that is perceived when cycling replaces walking represents (Chardon et al., 2017; Fishman et al., 2015; Qian and Wu, 2019). Even some commonly mentioned benefits of bike-sharing such as reduction of pollutant emissions, improvement in the traffic congestion, an increase of public transit ridership may not be true in all contexts (Fishman et al., 2014; Ricci, 2015).

Therefore, we can say that the success of a system will heavily rely on its context and that the solutions will have to be adjusted accordingly. However, it is possible to list, in a general way, some factors that are basic and can be considered as the ground where the systems should be built over. Below we list and briefly discuss some of the factors that we consider fundamental for the success of a PBSS.

Provision of Infrastructure

It is unquestionable that the success of cycling heavily relies on the provision of adequate infrastructure. On the one hand, the PBSS itself must guarantee that both the stations and the bicycles are easy to use and have good quality. It is also fundamental that the stations, in the case of SBBS, are well located and properly integrated into the urban environment (placed in safe locations and close to points of interest, not interfering in the free movement of pedestrians, protected from the general traffic, etc). The Institute for Transportation and Development Policy offers some guidelines on that matter stating that a well-located station should be no more than 300 m from each other (10–16 stations for every square kilometer) and a minimum of 10km² must be covered. The number of bicycles per 1000 residents should vary between 10 and 30 for optimal usage (ITDP, 2018).

On the other hand, it is also crucial that the municipality offers adequate public infrastructure such as bicycle lanes and parking areas that allow and facilitate cycling, thus, creating a friendly environment for PBSS use. The provision of an urban environment properly designed to accommodating cycling can substantially affect the ridership (Marqués et al., 2015; Ricci, 2015). Thus, the infrastructure has to connect the users not only with other stations but also with main landmarks and points of interest such as commercial centers, schools, universities, and residential clusters. Besides the convenience of the location, it also has to offer a safe environment for cycling protecting the cyclist from general traffic (Fishman et al., 2012).

In addition, to convenience and security, the infrastructure must consider the users' comfort. In cities where the natural environment is not encouraging to cycling (due to weather or hilly terrain), for instance, the issue can be minimized with the provision of special infrastructures such as sheltered, shaded, cooled, or heated cycle lanes or other solutions such as wide cycle lanes or even cyclocables, lifts or electric-assisted bicycles (Campbell et al., 2016). Hereupon, it is important to notice that all the infrastructures and operations are related to financial sustainability. Public Private Partnership approach is normally applied in many cities such as in New York, Paris, and London. YouBike system in Taipei, for example, has a 9 years concession to Giant Group with PPP approach in which the Taipei City Government provides funding of USD20 million for the infrastructure (vehicles and rental stations) while Giant Group takes the responsibility for operation (Chung and Huang, 2017).

Integration With Other Modes of Transport

The possibility to use bicycles is well known as a factor that may positively impact the attractiveness of public transportation, improving the users' convenience and efficiency perception (Martens, 2007; Krizek and Stonebraker, 2010; Sebok and Chang, 2018), especially when the distance between the origin or destination points and the public transportation station/stops is not considered short enough to be done by walk (Kittelson et al., 2003; Shaheen et al., 2010).

In this sense, to make the PBSS attractive, it is necessary to integrate it with the existing transit system creating an intermodal network that can provide door-to-door transportation. Thus, the increase of ridership and user satisfaction with PBSS can be achieved by the provision of docking stations or parking spaces connected or conveniently placed close by transit stations, especially when it is combined with a well-designed and consisted cycling infrastructure (Martens, 2004; Sebok and Chang, 2018). Moreover, the integration of PBSS with public transit can contribute to increasing the coverage of both systems, reducing in some cases the need for public transit systems expansion, hence, lowering the use of public resources. The provision of this intermodal network can enhance accessibility as people can reach places that are distant to be reached by walking (ITDP, 2018). In this sense, include PBSS into the Mobility as a Service plan is also an essential strategy for the success of both PBSS and MaaS (Chang et al., 2019).

Beyond the physical integration, it is relevant to consider the unification of payment. The use of universal rechargeable smart cards that can be used interchangeably to pay bus, rail, and PBSS trips is a good solution that is already being used in some cities to improve the service and user convenience (ITDP, 2018; Ji et al., 2017). In fact, the implementation of an easy-to-use registration and payment structure could be considered as a “success factor” itself as it is decisive for the success of a system. Registration and payment process should not only enable the integration of PBSS with the transportation network, but it should also bring solutions that favor small systems, tourists, and low-income users in a way that optimizes the usage while fostering equity.

Service Regulation

Another key element to increase the chances of success of a PBSS is the involvement of the government. As previously mentioned, the public power plays an important role as the provision of infrastructure for cycling is its responsibility. However, the infrastructure such as bicycle lanes and parking areas is not the only thing that public authorities should be in charge of. Governments should consider cycling as a fundamental part of urban planning and should take cycling as an indisputable part of the cities' Mobility Master Plan (Grafl et al., 2018; Liu et al., 2012).

In this sense, it is the government's responsibility to create, implement, and enforce regulations and policies that can guarantee the proper use of the urban environment. Besides the effective management of the public space, the regulations should establish the minimum requirements and standards to ensure the quality of the service that is provided by the private companies that operate PBSS schemes while fostering equity and accessibility as well as protect the users (ITDP, 2018).

As most systems operate through a Public-Private Partnership framework, the government can actively participate in all the stages of its implementation. Nevertheless, as before mentioned, there is no universal formula that can be applied to all the contexts and it is also valid when we talk about regulations. Thus, policies should address local issues.

In this sense, application of penalties and fines for users that did not comply with the regulations; delimitation of regions to be served and of maximum distance between stations; definition of desired density and the minimum number of bicycles per resident; description of minimum quality requirements for bicycles and stations, control of fare price or even permission to service providers implement a scheme of incentives to encourage the users to return the bicycles uphill when the city is not built over flat terrain or to a certain location as a way to foster social equity are valid (ITDP, 2018; Chardon, 2019).

Use of New Technologies

One of the reasons behind the quick spread of the PBSS over the world is the advance and popularization of technology. The development of new technologies and concepts such as the Internet of Things (IoT), Artificial Intelligence (AI), Information Communication Technology (ICT), Mobility as a Service (MaaS), Transit-Oriented Development (TOD) will strongly affect the future of PBSS.

The development of new technologies will facilitate the collection and processing of real-time big data. The possibility to use this type of data and the improvement and democratization of the use of existing technologies such as GPS, Internet, radiofrequency, and Bluetooth will enable a smart and customized management of the whole system including the real-time reallocation of bicycles, better integration of the system with the other modes of transportation or even among different systems of PBSS that operate within the same area, use of smart cards, solutions for easy registration and payment, implementation of electric or virtual fences to delimit parking areas, installation of smart lockers on the bicycles and use of e-bikes, and other smart solutions (Zhao et al., 2018; Zhang et al., 2019; Zhou et al., 2020). The use of these technologies may help to overcome some challenges that PBSS often face, thus enhancing user experience and service provider/government control. It is also worth noting that private sector involvement in PBSS development has allowed the flexibility of adopting new technologies for PBSS infrastructures and operations.

Provision of Information and Education

Cycling can bring numerous benefits, both to the individuals and the city as a whole. PBSS can play an important role, positively affecting the image of cycling, due to its potential to normalize bicycles as a mode of transport and cycling in general (López and Wong, 2017; Ricci, 2015).

Provision of information and education can be considered as a factor that may potentially contribute to the success of PBSS because it, directly and indirectly, affects the public perception about the system as well as the sense of safety, convenience, and satisfaction of the users. It is up to both the government and the service provider to promote campaigns and to employ marketing strategies to educate, inform, and encourage the use of PBSS, creating a good image of cycling.

Besides the provision of information and education to promote cycling and encourage the use of PBSS, it is also important to educate the general population, especially the drivers of motorized vehicles, as their disregard about cyclists can represent an increase in the accident levels involving cyclists and raises the PBSS risk perception (López and Wong, 2017).

Thus, governments and service providers should actively promote cycling, inform about its benefits, and educate all road users to respect the traffic laws and the regulations regarding the use of public space. It also includes the education of the cyclist about the safety of pedestrians, especially the ones that belong to vulnerable groups such as elders, people with disabilities, children, and pregnant women, for example. These initiatives can contribute to creating a safer and friendlier environment for cycling, which can increase ridership and the users' sense of safety (Grafl et al., 2018).

Beyond raising awareness about road safety and the benefits of cycling for the whole society, it is also fundamental that the public power acts assertively enforcing and punishing the road users that disrespect the laws or engage in negative behaviors towards the cyclists or the cycling infrastructure (Grafl et al., 2018; Unwin, 1995).

Conclusions

PBSS is a scheme that appeared for the first time less than six decades ago as a small initiative of a group of activists in the Netherlands. Since then, this scheme has passed for many improvements and it is now present in 85 out of the 195 countries

around the world. The system has evolved over these years passing through four generations. Along these years three different configurations of operation were proposed: with docks, without docks, and a hybrid version that combines the other two. All of these three configurations are still in operation, and in some cases, they coexist within the cities.

The quick dissemination of this type of system around the globe shows how popular this scheme has become. However, the systems also faced many challenges and in several situations, they ended up failing. Even though it is not possible to point out exactly which factors can lead to success in all the cases, it is possible to evaluate which general characteristics may have contributed to this success.

Given this, five factors have been identified as the key elements that may affect positively the chances of success of a system. The factors are the provision of infrastructure, the integration with other modes of transportation, the service regulation, the use of new technologies, and the provision of information and education. It is also worth mentioning that Private–Public Partnership approach is normally applied in development of PBSS.

Finally, we emphasize that the development of the PBSS is an ongoing process and that there is much more to learn and to understand about it while the system keeps evolving and the success cases consolidate over the years. Nevertheless, we believe that the overview of the system's importance, its historical overview, and these five factors that we listed here may contribute to paving the way in which new knowledge will be built over.

Introduction

Civil Aviation is a vital sector of the U.S. economy. In 2013, air transportation and related industries in the U.S. generated an output of 1.55 trillion dollars employing 10.5 million people (TEICAUE, 2011). The National Airspace System (NAS) provides a network of airspace, air navigation facilities, equipment, services (including information services), airports and landing areas, aeronautical charts, rules and regulations, procedures, technical information and personnel needed for the operation of civil aviation in the U.S. Included in the NAS are system components shared jointly with the military. In 2018, the NAS managed the progress of nearly 16.1 million flights with approximately 5000 flights in the air at any given moment. The capacity of the airspace in the current system is primarily limited by the ability of the air traffic controllers to maintain situational awareness and provide separation services to the aircraft. Additionally, wind, weather, and operational uncertainties add to the inefficiencies that result in traffic demand exceeding airspace and airport capacity. Traffic flow management initiatives such as holding aircraft on the ground, metering aircraft in the air and rerouting flights for mitigating demand-capacity imbalances result in significant delays, lost productivity, greater amount of noise pollution and increase in carbon dioxide and other greenhouse gas emissions. With the expected increase in traffic density and greater degree of automation in the future, airspace capacity will more likely be limited by the ability of the automation to detect conflicts between aircraft and to resolve them in a safe manner. Airport capacity will continue to be limited by the existing number and layout of runways and taxiways and by the inability to extend or construct new ones because of availability of land, public support and construction cost. Federal Aviation Administration (FAA) estimated the cost of delays to airlines in 2018 at 6.4 billion dollars (TEICAUE, 2011). The air traffic demand generally follows trends in the national economic growth. Air traffic demand went down during the years 2000–02, when the number of enplanements fell from 640 million to 574 million. It took another 2 years for the traffic to bounce back to its 2000 level. Currently, there is an unprecedented decline of between 56 and 60% in air traffic demand

due to the outbreak of corona virus (COVID-19) pandemic in China and its rapid spread to the rest of the world (ENC, 2020). The recovery of traffic from the effects of the pandemic depends on the ability of airlines to assure passengers that air travel is safe. Before the pandemic, the 2020 FAA forecast predicted the air traffic demand to grow over the next 20 years with an annual growth rate of about 2% (FAA, 2020). This anticipated increase in traffic will put a further strain on the airports and the airspace; it will result in large delays, airline schedule breakdown and adverse environmental impact.

The capacity improvements needed for meeting the future air transportation demand might not be achievable by incremental changes to the current operations. Major changes, including increased level of automation in a safety-critical environment with new roles for automation, controllers and pilots, are needed. To lead this transformation with the charter of planning and coordinating the development of the Next Generation Air Transportation System (NextGen), the United States Congress established the public--private multiagency Joint Planning and Development Office (JPDO) in 2003. This office included Department of Transportation, Department of Defense, Department of Commerce, Department of Homeland Security, FAA, National Aeronautics and Space Administration (NASA) and White House Office of Science and Technology. JPDO ended its mission in 2014. JPDO developed a comprehensive concept-of-operations (JPDO, 2009) that advocates operations based on four-dimensional aircraft trajectories. NASA continues to collaborate with the FAA and other industry partners to develop advanced automation tools to provide air traffic controllers, pilots and other airspace users accurate real-time information about traffic flow, weather and routing. The greater precision of this information is a key enabler of NextGen.

This article provides background about the current air traffic system and discusses new airspace technologies and efforts to introduce them to modernize the system to meet new challenges facing the air traffic system. The rest of the article is organized as follows. Section II provides an overview of operations typical of the air transportation system at the end of 2019, introduces air traffic control and traffic flow management and describes issues facing the 2019-era system. New concepts in air traffic management and the key challenges in designing the future system are described in Section III. Section IV describes the implementation of the advanced concepts in NextGen. Concluding remarks are provided in Section V.

Airspace Operations

Airspace operations are a distributed, hierarchical process with multiple decisionmakers. Airline flights operating under Instrument Flight Rules (IFR) are accomplished by the interaction of three participants: pilot, controller, and dispatcher. Fig. 1 shows the interaction between these three participants. The pilot is primarily responsible for safe operation of the aircraft. The controller is responsible for keeping the aircraft separated from all other aircraft in all phases of flight, including taxi on the airport surface, climb and descent in the terminal area, and climb, cruise and descent in en route airspace. Separation is assured by controllers talking to pilots via two-way radio, and pilots following their separation advisories. Like the pilot, the dispatcher is a certified airman. The dispatcher is responsible for flight, crew and maintenance schedules, creating and filing flight-plans, weight and balance, fuel, flight monitoring, separation of flight from severe weather, getting passengers to their destination, interacting with traffic flow managers and assisting the pilot with information and responses to their requests. Dispatcher and pilot communicate by voice via two-way radio and electronic messages via Aircraft Communications Addressing and Reporting System (ACARS), a digital datalink using airband radio or satellite.

The airspace over the U.S. is divided into 24 regions: 20 Air Route Traffic Control Centers (ARTCC a.k.a. center) in the Continental United States (CONUS), Anchorage Center (ZAN) and three Combined Center & Radar Approach Controls (CERAP)—Honolulu CERAP (ZHN), Guam CERAP (ZUA), and San Juan CERAP (ZSU). The centers in the CONUS are shown in Fig. 2. The center airspace is subdivided into sectors (ETMS, 1999; Nolan, 2000). For example, the high-altitude sectors in the

Figure 1 Air traffic management operations.

Figure 2 Centers in the Continental US with Sectors shown for Oakland Center (ZOA).

Oakland Center (ZOA) are depicted in the insert appearing on the left side of **Fig. 2**. Air traffic controllers always keep the aircraft in their sectors separated from each other; they handoff aircraft from one sector to another within the center and then to a sector in the neighboring center as flights traverse the center airspace. Traffic flow managers in the center impose traffic flow controls to protect the air traffic controllers in the sectors from being overwhelmed by traffic demand. They coordinate with the neighboring centers and the Air Traffic Control System Command Center (ATCSCC a.k.a. Command Center), located in Warrenton, Virginia, to impose metering restrictions on inbound traffic from neighboring centers. They also interact with sector controllers within their center to ensure that the controller's handoff outbound traffic according to the metering schedules coordinated with the receiving centers. Traffic flow managers at the centers are also responsible for coordinating metering of arrival and departure traffic to and from airports transitioning through the terminal area.

Two major functions associated with Air Traffic Management (ATM) are Air Traffic Control (ATC) for keeping aircraft separated from each other and Traffic Flow Management (TFM) for maintaining efficient flow of traffic. These two functions must be performed while (1) preventing airport and airspace capacity constraints from being exceeded by demand and (2) reducing environmental impact of aircraft emissions. The task of detecting conflicts (potential loss of separation) and resolving them is referred to as "Separation Assurance," which is performed by air traffic controllers with the help of decision support tools. TFM is the planning of initiatives to prevent traffic demand from exceeding airport and airspace capacities and redistribute demand for effective use of the available capacity. Strategic plans for TFM are developed throughout the day by the ATCSCC following a Collaborative Decision Making (CDM) process with centers, terminal facilities, airports and aircraft operators guided by predictions of national traffic flows resulting from forecast demand and weather conditions. Airline schedules, route preferences and operational objectives of the different stakeholders are factored into the CDM process (Ball et al., 2001). Resulting plans might call for delaying some flights at airports and rerouting others. Dispatchers interacting with air traffic coordinators at airlines respond to Traffic Management Initiatives (TMI) by amending flight plans, rescheduling, substituting and canceling flights.

Air Traffic Control

Air traffic controllers have always used cognitive analysis supported by tools for display of track history and trend vectors (short duration forecasts) for determining conflicts between pairs of aircraft and developing strategies for resolving them. Using voice communication, they issue an advisory to the pilot, such as climb, reduce speed, or change heading to resolve conflicts. Modern Decision Support Tools (DSTs) deployed in recent years provide trajectory-based advisory information to assist controllers with conflict detection and resolution (Erzberger, 2004, 2006) and arrival metering. Trajectories are predicted by employing models of aircraft performance and the atmosphere, wind data, flight plan and track data. The flight plan defines the horizontal path from origin to destination, cruise altitude and cruise speed. The aircraft performance model specifies takeoff weight, thrust, drag, fuel burn, climb and descent calibrated airspeed and speed and altitude thresholds for transitioning from one flight mode to the next such as from climb to cruise and approach to landing.

The atmosphere model provides parameters such as density of air, temperature, speed of sound and static pressure as a function of altitude that are used in the aircraft performance model. The airspeed of the aircraft is obtained from the aircraft performance model in the climb and descent phases. It is estimated using groundspeed and course heading, derived from track data, and wind data in the cruise phase of flight. The estimated airspeed and the wind forecast are then used to forecast groundspeed along the planned route of flight. The course heading for the horizontal component of the forecast trajectory is estimated assuming (1) the aircraft will continue flying along the flight plan route starting from its current position or (2) it will continue flying along its current path as indicated by its recent track history. The horizontal component of the trajectory is predicted by propagating the latitude and longitude forward in time using the course heading and groundspeed in the equations of motion. The vertical component of the trajectory is similarly predicted by propagating the altitude forward in time using the climb and descent rates obtained from the aircraft performance model for climb to cruise altitude and for descent past the top of descent point. Climb rate is set to zero past the top of climb point and prior to the top of descent point for predicting the vertical component of the trajectory in the cruise phase of flight.

Conflicts between aircraft are determined by computing the distance between the forecast trajectories at discrete intervals along the trajectories and checking if the minimum separation between them is less than or equal to the minimum separation standard. Once a conflict is determined, a process called trial planning is initiated to resolve the conflict. Trial planning, as the name suggests, uses the trajectory prediction capability repeatedly with different values of control variables—speed, heading, altitude and combinations of them—for creating alternative trajectories. These trajectories are examined for conflicts using the conflict detection procedure. Control variables associated with trajectories that do not result in conflicts are chosen as acceptable conflict resolution maneuvers. These options are then displayed on the DST as choices to the controller for providing advisories to the pilots.

Although these DSTs improve safety and reduce delays, human-centered automation limits the capacity of a sector to about 15 aircraft, a number far below that required by legal separation, because of a human controller's cognitive ability to maintain situational awareness and safety of traffic in the sector (Sridhar et al., 2011). A fundamental transformation in the way separation assurance is provided is necessary to achieve the capacity gains necessary for meeting future growth in demand.

Traffic Flow Management

The complexity of the TFM problem and the duration of the planning interval leads to a natural decomposition of the problem into national TFM decisions performed by the Command Center providing guidance to centers or groups of centers (regions) and regional TFM decisions performed in the regions. Regional TFM plans are detailed plans for the region for a short duration of time. They are implemented using near-term traffic and weather information.

National Traffic Flow Management

The goal of national traffic flow management is to prevent the traffic demand from exceeding the available capacity of NAS resources because exceeding capacity directly affects safety. TFM imposes flow restrictions following the CDM process for accommodating user preferences. TFM is often required during severe weather conditions because weather reduces both airspace and airport capacity. Predictions of weather and traffic demand in the airspace and at airports are employed by the ATCSCC to form strategic plans from an hour to 24-hour time horizon (FAA, 2008). Some of the mechanisms employed for national TFM are Airspace Flow Program (AFP), Ground Stop (GS), Ground Delay Program (GDP), and National Playbook. AFP identifies flights scheduled to travel through a capacity constrained airspace such as a region impacted by severe weather. The impacted flights on the ground can either take delay waiting at the airports or takeoff and take the delay while airborne. Depending on the extent of the constraint, flights might be allowed to travel through the constrained area or be required to circumvent it. While AFP is primarily used for responding to en route constraints (it can be used for constraining flows into and out of airports), GDP and GS are used for responding to airport constraints. GS holds all flights destined to an affected airport at their airport of origin for the duration of the GS initiative. Unlike GS, GDP issues a departure clearance time to aircraft scheduled to arrive at the capacity constrained airport using a Ration-By-Schedule (RBS) procedure. RBS spaces out aircraft arrivals in time to reduce the arrival rate according to the limited airport capacity. The difference between the RBS scheduled arrival time and the airline provided arrival time—delay—is added to the airline provided departure time to determine the departure clearance time. Aircraft are expected to takeoff within 5-minutes early or late (a 10-minute window) with respect to the assigned departure clearance time.

The FAA employs the National Playbook (FAA, 2008), which is a compendium of standardized alternative routes for circumventing defined regions of airspace based on historically validated data, as a part of its Severe Weather Avoidance Plan (SWAP) and for mitigating equipment outage impact. Fig. 3 shows the *CAN RUBKI EAST 1* West to East transcontinental route from the Playbook for routing eastbound traffic through the Minneapolis Center when a large portion of airspace in the Midwest is affected by weather. The large rectangular region in the southern portion of Minneapolis Center (ZMP) represents a predicted severe weather region. The routes represented with a solid line in this figure represent alternative routes for aircraft originating on the West Coast and traveling to East Coast destinations such as Boston (BOS), La Guardia (LGA), and Dulles (IAD).

Regional Traffic Flow Management

Regional traffic flow management, which operates on a 20-min to 2-hour time horizon, adjusts flow control actions based on near-term forecast of air traffic demand, airspace capacity and weather while preserving the national flow management objectives set by the Command Center. These adjustments are made by Re-Routing (RR) flights, distancing flights spatially with Miles-In-Trail (MIT)

Figure 3 Graphical representation of the CAN RUBKI EAST 1 route with a conceptual region of severe weather depicted by the shaded polygon.

and distancing them temporally with Minutes-In-Trail (MINIT). Distancing has the effect of reducing the number of aircraft entering the region; the number entering is inversely proportional to the MIT and MINIT. MITs are set in increments of five miles with a typical value between 10 and 30 miles. MIT and MINIT restrictions are used both in the en route and terminal airspaces. They are routinely used along center boundaries to control (meter) the inbound and outbound flow rates. However, they can be applied at any location where metering is desired including along lines and arcs demarcating airspace. The centers requesting the restriction set the inbound rates while the centers enforcing the restriction constrain the outbound traffic flow rate to comply with the requested restriction. The local MIT and MINIT restrictions are coordinated with the Command Center for a common system-wide awareness of TFM initiatives.

Fig. 4 shows the outcome of the national and local TFM actions on flights on a day affected by severe weather. Each dot in the display indicates a flight in the NAS. Gray, blue, and red dots indicate on-time flights, flights delayed between 15-minutes and 2-hours and flights delayed by more than 2 h, respectively. While delays due to TFM initiatives are unavoidable especially on days affected by severe weather, the efficiency of TFM decisions can be improved by timely sharing of information between decision-makers (Wambsganss, 1997). Airlines being fully aware of the traffic conditions and the status of the NAS in making their rerouting, rescheduling and cancellation decisions and the TFM decision support tools having the data associated with these decisions in a timely manner result in greater accommodation of user preferences and reduction of delays. This is the main motivation for the FAA and the aviation industry for developing the CDM process. The FAA has also invested in providing real-time and near real-time system-wide air traffic data to the stakeholders via the System-Wide Information Management (SWIM) data feed starting with the completion of Segment 1 in 2015—to foster common understanding and to aid decision-making. While the CDM process is effective for strategic decision-making, user participation is somewhat limited for short-term planning because of the time available for decision-making and for implementing tactical decisions, leading to inefficiency.

Other reasons for inefficiency are business and human decision-making related. For example, takeoff weight of the aircraft, which is an important parameter especially for climb trajectory prediction (Krozel et al, 2003), is not provided by the operator for business reasons because knowledge of the takeoff weight along with the type of aircraft and route of flight could be used by a competitor to estimate the load factor—number of passengers carried by the flight. TFM decisions made by human traffic managers, while aided by computational tools, are dictated primarily by experience and safety considerations and not by optimality. It might be possible to

Figure 4 Traffic display with on-time flights in gray, aircraft delayed between 15 min and two hours in blue, and aircraft delayed more than 2 h in red.

better utilize the capacity of the NAS by considering the national and regional initiatives as parts of a single integrated optimization problem. TFM optimization has been formulated as a mixed-integer linear problem and efficient computational techniques have been developed for solving it (Bertsimas and Patterson, 1998; Rios and Lohn, 2009; Sengupta et al., 2005). The main difficulty in using these solutions operationally, however, is that these solutions provide controls such as delay and speed reduction for each aircraft; it is difficult to translate the solution to flow controls. In fact, the optimization problem for transforming the disaggregated controls for individual aircraft to aggregated flow control is of the same size and complexity as the original problem for generating the disaggregated controls (Sun et al., 2010). The scalable computational hardware and software platforms based on cloud technologies promise to make these optimization solutions more practical in the future.

Terminal Area Operations

The average spacing or distance between aircraft for ensuring safety with human-centered control limits capacity at the airports and within en route airspace. Spacing is influenced by the separation standards and the ability of the Air Navigation Service Provider to precisely control to those standards. Both are influenced by the technologies and procedures employed by controllers for tactical (20-minute time horizon) air traffic management and by pilots for complying with the resulting advisories. Improving the efficiency in the terminal area, which is the volume of airspace within a radius of about 50 miles surrounding airports, is especially difficult due to the differences in the operating characteristics compared to that in the en route airspace. Terminal area controllers manage both climbing and descending aircraft operating in the proximity of terrain and close to each other in a high traffic density environment. Due to the small size of the terminal area compared to the high-altitude airspace, both the time and space available for aircraft maneuvers for conflict resolution and for absorbing delays, especially for metering arrivals to airports, is short.

In today's terminal area arrival operations, as an aircraft descends for landing, controllers track and guide the aircraft all the way to the runway using visual and data aids provided by terminal automation systems such as the Standard Terminal Automation Replacement System (STARS) as well as their skills and judgment. They issue turn-by-turn instructions (a process known as vectoring) to the pilot via voice communications. As aircraft fly towards the airports, controllers instruct the pilots to merge aircraft into arrival flows and sequence them for arrival. Busy terminal area conditions often force the aircraft to fly inefficient arrival routes requiring frequent changes in direction, altitude and speed. Controllers are forced to ask aircraft to fly a longer path—path stretching advisory—or remain in a holding patterns to absorb larger amounts of delay. These maneuvers cause additional fuel burn and noise. They also increase controller workload by exacerbating traffic congestion and requiring them to monitor the aircraft during these off-nominal maneuvers and return them back to their intended routes. The uncertainties in the system force controllers to add spatiotemporal buffers for separation, which decreases airspace capacity, leading to further delays.

While more efficient arrival paths can be flown, currently deployed technology and procedures limit their use to light traffic conditions such as during night. As density of traffic increases, maintaining safe separation with a human-centered system will continue to take precedence over efficiency. Making efficient arrival procedures a common practice during heavy traffic, when they are needed most, while ensuring safety remains a technical challenge.

The arrival and departure capacities at the busiest airports will continue to play a key role in determining the efficiency of the NAS and will ultimately limit the growth of air traffic. To accommodate the traffic anticipated by NextGen, the arrival/departure capacity must increase at the large airports and regional airports, and number of operations must increase at the underutilized and smaller airports. The JPDO envisioned new technologies for enabling significant growth at large airports.

Surface Traffic Operations

The surface operation at many major airports in the U.S. is conducted by airlines controlling the ramp area (also known as the "nonmovement area") and by the FAA controllers in the Air Traffic Control Tower (ATCT) controlling traffic on taxiways and runways. Airline ramp controllers coordinate pushback of aircraft from their gate based the scheduled departure time and pilot readiness for departure. The difference of the actual gate pushback time with respect to the scheduled gate pushback time is tracked as a metric of system performance. Ramp control is responsible for the aircraft leaving the gate to stay separated prior to entering the movement areas. Because gate departure time determines the entry time at the spot (the location demarcating the boundary between the ramp area and taxiway), into the taxiways and eventually arrival at the runway, uncoordinated gate release times especially during busy conditions result in taxiway congestion and large runway entry queues (Balakrishnan and Jung, 2007; Malik et al., 2010; Rathinam et al., 2008).

Once the ground controller gives permission to the pilot to enter the movement area, the aircraft leaves the spot and enters the taxiway. The ground controller is responsible for separation of aircraft and vehicles on airport movement areas except on the active runways. The ground controller issues instructions to the pilots to safely taxi to the runway. Pilots contact the local controller prior to crossing an active runway and for permission to enter the designated runway for takeoff. The local controller sequences this flight into the local flow while ensuring that the aircraft is separated from the other inbound and outbound aircraft. The local controller clears the flight for takeoff and instructs the pilots to contact the departure controller at the Terminal Radar Approach Control (TRACON).

Like the gate pushback delay, taxi-out time delay is also a metric of airport performance. Taxi-out time is defined as the difference between when the aircraft leaves the gate/spot and its takeoff time. The excess taxi-out time with respect to the average of unimpeded taxi-out time for the airport is defined as the taxi-out delay. A study in 2007 estimated the taxi-out delay to be 6.8 min per departure

considering all U.S. airports and higher than 15 min per flight for the three major airports in New York (Guilding et al., 2009). During January 2016, the FAA Aviation System Performance Metrics database reported taxi times that, in Los Angeles airport (LAX), 1% of the flights experienced more than 40 min of taxi times and the average taxi times was 15.73 min per flight. An analysis of fuel consumption at the Dallas/Fort Worth (DFW) airport showed approximately 7000 gallons/day is spent because of stop-and-go during taxi.

The efficiency of NAS can be improved by better coordination of arrival, departure and surface traffic. The coordination is complicated by the fact that all airports are unique, and their distribution of responsibility amongst airlines, airport authorities and the FAA, makes the coordination more challenging, and difficult to apply a monolithic solution. Pre-departure coordination between several operational positions within the ATCT and Traffic Management Units (TMUs) at both the associated TRACON and the ARTCC serving the departure airport is currently done by phone calls, manual data entry and the use of restrictions such as a Miles-In-Trail (MIT) or Minutes-In-Trail (MINIT) for flights crossing a departure fix (Doble et al., 2009). The extent of coordination needed depends on the complexity and activity level of the departure airport, number of other airports within the terminal area, merging of departures with overhead traffic flows, the presence of convective weather in the terminal area or en route and constraints at the destination airports.

The FAA has developed a suite of capabilities to improve departure congestion management. One of them is the TFM Surface Data Integration (TSDI), which processes airport data from various automation and surveillance systems (e.g., Airport Surface Detection Equipment (ASDE), Electronic Flight Strip Transfer System, Automatic Dependent Surveillance-Broadcast (ADS-B) and airline-provided event data) to produce information on actual surface events, predicted events and metrics. This standardized information is intended for integration into TFM decision support tools.

Advanced Airspace Operations Concepts

The ATM system supports operations during all phases of flight starting from gate pushback at the departure airport, taxi, takeoff, climb, cruise, descent, approach, landing and taxi to the gate at the arrival airport. This is accomplished by using surveillance, separation standards and decision support systems tailored for airport surface movement, flight in the terminal areas and in en route airspace. The ATM system has embraced digital transformation for quite some time upgrading and modernizing hardware and software-based systems for managing air traffic. The transition from a largely manual system to a computer-based system has been an ongoing endeavor. With increasing automation and especially that required for accommodating highly-automated pilotless aircraft operations in the NAS, major challenges in the future will be: (1) the appropriate human/automation mix, (2) graceful degradation with transfer to human control when automation fails, and (3) reliance on aircraft operators and their service providers with roles and responsibilities for managing the safety of air traffic operations. The expected evolution from a centralized—single provider of ATM service—to a decentralized system with multiple providers is shown in Fig. 5. Successful transition will depend on meeting the human-automation challenges.

The near-term focus of the FAA will stay on the NextGen modernization program, which is responsible for implementing major new technologies and capabilities with the objectives of improving safety, efficiency and predictability. The multiyear NextGen investment and implementation plan is almost halfway done; it calls for continued deployment of cutting-edge technologies, procedures, and policies through 2025 and beyond. Several NextGen technologies are described below in Section IV.

The future ATM system will need to accommodate operations with new types of vehicles such as very light jets, unmanned aircraft systems (UAS) and commercial space launch vehicles. The developments in Urban Air Mobility (UAM)—on demand flights with two to six passenger aircraft—and Unmanned Aircraft System (UAS)—package delivery drones—will introduce a large amount of low altitude air traffic into the NAS. NASA and the FAA have been developing operational concepts for the safe and efficient integration of the operations of these new classes of vehicles. The architecture developed under NASA's UAS Traffic Management (UTM) project with air traffic services provided by multiple organizations is considered a model for developing UAM air traffic

Figure 5 Transformation of ATM systems.

services. The FAA has recently released the concept-of-operations for UAM flight operations (ConOps 1.0) (FAANGO, 2020). UAM is a subset of the Advanced Air Mobility (AAM) initiative of NASA, FAA and industry for developing the future air transportation system for serving local, regional, intraregional and urban areas with new electric vertical takeoff and landing aircraft. The envisioned end state of UAM operations depends heavily on autonomy. Initial operational experience will be gained with new vehicles certified under the current regulatory frameworks, which are expected to evolve as UAM operations increase. Eventually, routine operations are expected to introduce new rules and regulations, infrastructure and automated vehicles, operational control and traffic management systems. Several emerging technologies are summarized in Section V.

In addition to enabling operations with new types of vehicles, enhancements will continue for improving safety and efficiency with growing demand for commercial high-altitude traffic in the future. Better sharing of data and decisions across different systems employed for airport surface, terminal and en route airspace traffic flow management and air traffic control offer the potential for eliminating unnecessary restrictions and uncoordinated decisions, thereby, reducing delays and fuel consumption and increasing utilization of capacity constrained airport and airspace resources. Several of these technologies in various stages of development and evaluation are outlined in this section.

Integrated Demand Management

Integrated Demand Management (IDM) (Smith et al., 2016) is a near to midterm Trajectory Based Operation (TBO) concept to collaboratively organize aircraft trajectories into well-managed flows that match traffic demand to available capacity. The concept seeks to leverage FAA and NASA pre-departure, en route and arrival technologies. IDM uses Traffic Flow Management System (TFMS) tools to pre-condition traffic into the Time-Based Flow Management (TBFM) system, enabling TBFM to better manage delivery to the capacity-constrained destination. TFMS is used operationally by the FAA to (1) forecast air traffic demand in the airspace sectors and at airports based on airborne flights and flights scheduled to depart in the future and (2) to develop traffic flow management initiatives such as altering departure time, increasing the temporal or spatial separation and increasing the length of the flight route to balance the demand with respect to the available capacity. As opposed to TFMS, which is employed for longer-term planning, TBFM is used by the FAA for short-term arrival and departure traffic flow management. TBFM assigns arrival slots at metering locations such as meter fixes, meter arcs and runway threshold based on estimated time of arrival of flights, separation rules and the arrival rate set by the airport. TBFM also enables air traffic controllers to reschedule internal departures—from airports located within some distance from major airport—to fit into the overhead stream of arrivals to the major airport based on their calculated Scheduled Times of Arrivals at the metered locations.

The IDM approach is expected to benefit airlines by reducing fuel consumption because of holding aircraft on the ground as opposed to in the air. One component of IDM that is currently being investigated is the use of Flow Constraint Areas (FCA) at the TBFM boundary to which Required-Times-of-Arrival (RTA) are generated (Yoo et al., 2016). These FCA rates are set based on downstream airspace and airport capacity constraints. IDM accommodates user preferences using the Collaborative Trajectory Options Program (CTOP) capability of TFMS. CTOP is a procedure for managing traffic demand using FCAs while accounting for user route and delay preferences specified via Trajectory Options Sets (TOS). As opposed to a single flight plan request, TOS enables the flight operator to request multiple flight plans with different routes, altitudes and speeds. Options within the TOS might contain “start” and “end” times for operational acceptability of each flight plan option. This enables CTOP to rank the TOS options based on the extent of delay required for mitigating demand-capacity imbalance. CTOP then assigns either a route to go around the FCA or a route and departure time—Expect Departure Clearance Time (EDCT)—to arrive at the scheduled slot at the FCA. The operator is expected to file a flight plan with the assigned option. Aircraft assigned an EDCT in CTOP are exempt from additional delays by policy except as required by miles-in-trail and departure and en route spacing approved by the ATCSCC.

Integrated Arrival/Departure/Surface Metroplex Traffic Management

Some of the inefficiency in today’s system stems from impediments in information sharing for effectively managing traffic in busy terminal areas. While technologies for improving the arrival, departure and airport surface traffic operations have been under development for quite some time, NASA’s recent Airspace Technology Demonstration-2 (ATD-2) initiative seeks an integrated approach with information sharing across airlines, air traffic service providers, airport authorities and technology vendors to improve predictability of aircraft movement times on the airport surface and in the airspace to reduce fuel burn and emissions. Several of the inefficiencies targeted by ATD-2 include untimely pushback from the gate and uncertainties in prediction of taxi, takeoff, and climb times. Uncoordinated pushback from the gate can cause congestion on the taxiways and long runway queues resulting in delays. Inability to predict taxi, takeoff and climb times reasonably accurately leads to inaccurate prediction of time of arrival at metered locations, and therefore, to inaccurate traffic demand at constrained resources. This often results in overly conservative traffic flow management initiatives.

ATD-2 integrates arrival, departure and surface (IADS) concepts for traffic management in a metroplex environment (Jung et al., 2019). The technologies will increase predictability of the air traffic system and enhance operational efficiency, while maintaining or improving throughput. IADS combines multiple concepts and technologies, including the FAA’s three operational

decision support tools (TFMS, TBFM, and Terminal Flight Data Management (TFDM)), as well as the NASA's Spot and Runway Departure Advisor (SARDA) and Precision Departure Release Capability (PDRC) technologies. SARDA was developed to improve the efficiency of airport surface operations through time-based metering of aircraft and improved situational awareness amongst stakeholders, while PDRC coupled a trajectory-based decision support functionality with the tactical departure scheduling capabilities of TBFM, resulting in more precise scheduling of surface departures into constrained overhead flows. Based on ready times of aircraft at the gate, the Surface Trajectory-Based Operations (STBO) tool, which incorporates both SARDA and PDRC, schedules pushback times for departures for communication to a tool for the airline operators in the form of a Ramp Traffic Console (RTC). Outbound scheduling of departures under TBFM scheduling to another airport (typically internal departures) is coordinated with the TBFM system scheduling those departures.

Applied Traffic Flow Management (ATD-3)

The technical challenge for NASA's ATD-3 subproject (Gong, 2020) was to "reduce weather-induced delays through integration of weather information to better manage aircraft, traffic flow, airspace and schedule constraints by delivering air-ground procedures and user-tool technologies." The key technologies for achieving the ATD-3 technical challenges were: Multi-Flight Common Route (MFCR), Traffic Aware Strategic Aircrew Requests (TASAR) and Dynamic Routes for Arrival in Weather (DRAW). MFCR is concerned with automatically searching for efficient weather avoidance routes (in terms of fuel and time) and unnecessary weather avoidance routes imposed by earlier traffic management initiatives that are no longer needed due to changes in weather conditions. Avoiding unnecessary reroutes reduces delay. TASARs focus is flight-deck-based automated continuous search for efficient reroutes in the airborne phase for reduced fuel consumption and flight time while avoiding traffic, weather and restricted airspace. DRAW seeks to find efficient en route weather avoidance routes for arrival flights while complying with meter-fix capacity constraints. The DRAW algorithm computes weather avoidance routes for flights that are predicted to be in conflict with weather and provides these routes to a scheduler. The timeline generated by the scheduler shows the estimated arrival times of the rerouted flights in relation to the other flights and the available slots. The trial planning process consists of iteratively creating routes and determining the schedule impact until the desired route and schedule are found to be acceptable to traffic flow managers. An application of DRAW is balancing the demand between the arrival meter-fixes. The ATD-3 Integrated Concept utilizes MFCR, TASAR, and DRAW to create a departure to arrival route solution.

Environmentally Friendly Operations

Aviation affects the environment in terms of noise, air quality, water quality and climate (IPCC, 1999). It is estimated that aviation is responsible for 13% of transportation-related fossil fuel consumption and two percent of all anthropogenic Carbon Dioxide (CO₂) emissions (Brasseur and Gupta, 2010; Lee et al., 2009). Although this contribution is small, a large portion of the emissions takes place at higher altitudes where they remain longer compared to that emitted at the surface. The desire for growth in air traffic while limiting the impact of aviation on the environment has led to research in green aviation. The goals of green aviation are better scientific understanding, utilization of alternative fuels, introduction of new aircraft technologies—engine and airframe—and operational changes. Aviation operations affect the climate by injecting the by-products of the combustion of fossil fuel—Carbon Monoxide (CO), CO₂, water vapor, oxides of nitrogen (NOX) and particulate matter—into the atmosphere. Among the constituents of engine exhaust, CO₂ and water vapor are Green House Gases (GHG) that perturb the balance between incoming solar radiation and outgoing infrared radiation at the top of the troposphere. This perturbation is called Radiative Forcing (RF); GHGs result in positive RF. Higher concentration of GHGs causes higher amount of infrared radiation to be trapped in the atmosphere. Global mean surface temperature change varies approximately linearly with RF. Because of its abundance and long lifetime, CO₂ has a long-term effect on climate change compared to the non-CO₂ emissions. Water vapor and the particulate matter in the exhaust cause the formation of condensation trails (contrails) (Duda et al, 2003), which can then lead to the formation of cirrus clouds. Contrails and cirrus clouds reflect the infrared radiation received from the Earth's surface back to the surface. Some estimates suggest that contrails might be causing more climate warming today than all the residual CO₂ emitted by aircraft (Boucher, 2011). Methods have been proposed for eliminating contrail formation such as flying at a different cruise altitude and rerouting around regions of airspace with temperature and humidity conditions favorable for persistent contrail formation (Williams et al., 2002). However, these solutions however come at the cost of longer flight time and cruise at nonoptimal altitude, resulting in increased fuel consumption and therefore CO₂ emissions.

To estimate the impact of aviation contrails in the U.S., simulation-based studies have been conducted. For example, Ref. 34 employed the process summarized in Fig. 6. This process consists of (1) simulating air traffic, (2) predicting contrails, (3) predicting emissions, and (4) generating alternative trajectories to reduce the environmental impact. Air traffic is generated by simulating flight trajectories along the path prescribed in the flight plans using aircraft performance models, derived from Eurocontrol's Base of Aircraft Data (BADA), and wind data. These trajectories and predicted temperature and humidity data are used to predict the contrails. The fuel burn and emissions model are then used to generate estimates for the simulated trajectories. Finally, alternative trajectories are created to circumvent regions that are conducive to contrail formation. The procedure in Fig. 6 can be applied to present and future traffic scenarios. It can also be used to evaluate the energy efficiency of contrail reduction strategies and tradeoff between persistent contrail mitigation and fuel consumption for policy makers to set aviation operation guidelines.

Figure 6 Simulation capability to evaluate impact of aviation emissions and contrails.

Performance Based Navigation (PBN) enabled by satellite and other communication technologies being introduced in the NAS frees aircraft from ground-based navigation, which makes it possible to fly fuel-efficient and environmentally friendly routes adjusting dynamically with changing atmospheric conditions. Part of the motivation for introducing new technologies and procedures is a carbon neutral growth in the fzaand reduction of climate impact of aviation emissions in the long-term (2050).

In addition to emissions and impact of contrails, noise reduction is an important environmental goal. Noise from aircraft has direct health, social and economic impacts to local residents and communities near the airport vicinity. It is one of the leading aviation-induced environmental issues that have been studied for decades. In U.S., about 500,000 people today are affected by aircraft noise based on the FAA's Office of Environment and Energy's standard, i.e. people that live in the area where the Average Day-and-Night Sound Exposure Level over 24 h (DNL) is 65dB or more. 65 dB DNL is recommended as threshold of compatibility with residential land use. However, experts have suggested a lower level of 55 dB DNL as "level of environmental noise requisite to protect the public health and welfare with an adequate margin of safety" (1972 Noise Control Act) (SAE, 1986). The anticipated growth in air traffic will result in an increased number of people affected by aircraft noise. There are mainly two ways to reduce aircraft noise impact on the environment. One is through developing noise-reduction aircraft engine technologies (Hileman et al., 2007). The other is by redesigning currently operated terminal routes to mitigate the aircraft noise impact while ensuring safety and throughput. To reduce the impact of noise near airports, arrival and departure routes and procedures are prescribed to ensure that the flights taking-off and landing leave a small noise footprint on the population below (Alam et al., 2011; Xue and Athins, 2006).

NextGen Implementation

The NextGen portfolio of projects seeks to plan and implement improvements to infrastructure, new innovative technologies and procedures to modernize the air transportation system. This section describes some of the mature concepts and technologies that are being considered for implementation (FAA, 2019).

Automatic Dependent Surveillance-Broadcast (ADS-B)

ADS-B (FAA, 2013) is expected to transform air traffic control by providing surveillance information directly from the aircraft as opposed to indirectly from the current radar-based systems, providing surveillance information in oceanic airspace and in remote locations lacking radar coverage such as the Gulf of Mexico and parts of Alaska, providing traffic data for display on the onboard Cockpit Display of Traffic Information (CDTI) system for improving pilot situational awareness and by promoting better controller and pilot decisions with common situational awareness. ADS-B capable aircraft derive their position from the onboard systems such as the Global Positioning System (GPS) and broadcast their position along with state variables such as speed, heading and altitude, and short-term intent information—consisting of locations of the next several waypoints describing the planned route—using satellite communication. The broadcast information can be received by other ADS-B capable aircraft and ATC in real time. ADS-B consists of two different services: ADS-B Out and ADS-B In. ADS-B Out is the capability for periodically broadcasting information and ADS-B In is the capability for receiving traffic and weather information data from nearby-aircraft and ground-based systems. Vehicle position data provided by ADS-B, and displayed on cockpit and controller displays, has been found to reduce the risk of runway incursions and collisions especially during nighttime and low visibility conditions on the airport surface. ADS-B is also expected to help reduce separation between aircraft, which will lead to increasing airspace capacity.

The FAA has integrated ADS-B into automation platforms at all 24 en route air traffic control facilities and into most of the TRACON facilities, including the 30 busiest terminal areas in the U.S. They plan to integrate into the remaining terminal area automation platforms as the platforms are updated. The FAA has engaged with several airlines to obtain ADS-B data to validate the business case for early adoption. The FAA mandated aircraft need to be equipped with ADS-B Out capability to operate in Class A, B, C and E airspace after January 1, 2020. Currently, there is no mandate for aircraft to be equipped with ADS-B In capability.

Figure 7 Aircraft with RNAV capability of RNP 2.

Table 1 PBN requirements during different phases of flight

Oceanic	RNP 10, RNP 4
U.S. En route	RNP 2
Terminal Area	RNP 2, RNP 1
Approach in Instrument Meteorological Condition (IMC)	RNP 0.3

Performance-Based Navigation (PBN)

Area Navigation (RNAV) is a method of navigation that enables an aircraft to fly along a desired flight path within the coverage of the navigational aids, within the limits of the aircraft or a combination of both. RNAV capable aircraft can fly directly between points in the airspace rather than from navigation aid to navigation aid. Safety along an RNAV route is ensured by a combination of aircraft navigation accuracy, route separation, and ATC radar monitoring and communications. Required Navigation Performance (RNP) is a navigation accuracy requirement that RNAV capable aircraft—equipped with onboard avionics—can monitor and comply with during flight. The Performance Based Navigation (PBN) concept assumes the navigation accuracy specification is met using a combination of ground-based, satellite-based and aircraft-based hardware and software. RNP specifies the cross-track accuracy between the desired and actual trajectory of the aircraft. As shown in [Fig. 7](#), an aircraft with RNAV capability of RNP 2 should be able to follow the desired trajectory with a cross-track accuracy of two nautical-miles 95% of the time and within a lateral containment region of four nautical-miles 99.999% of the time. RNP values ranging from 10 to 0.1 nautical miles are typically used. Lower values such as RNP 0.1 are specified for Authorization Required (AR) approaches for instrument landing. [Table 1](#) shows some of the commonly used RNP during different phases of flight.

RNAV routes not based on VOR routes in low altitudes are preceded with the letter “T”; high altitude routes are designated with the letter “Q”. In addition to the PBN requirements listed in [Table 1](#), aircraft on Q-routes on flight levels (FL—altitude in 100s of feet) between 180 (18,000 feet altitude) to 450 and T-routes below FL 180 have a requirement of RNP 2. In the en route airspace, PBN provides more efficient routes around convective weather, increased airspace capacity using multiple Q-routes, direct routes between city/terminal area pairs and reduction in delays. T-routes provide benefits by enabling flight through or around Class B and C airspace.

The benefits of increased capacity and reduction in noise and emissions in the terminal area are accrued by using integrated Standard Terminal Arrival Route (STAR) and RNP approaches and optimized profiles and by decoupling flows between primary and satellite airports.

The realization of the benefits of PBN depends partly on aircraft equipage ([Devlin et al., 2009](#)). PBN requirements can be realized using navigational systems such as RNAV capable Flight Management System (FMS), Non-RNAV system capable of supporting RNP and non-FMS RNAV navigation capability and sensors such as Distance Measuring Equipment (DME), Inertial Reference Unit (IRU) and GPS. The RNP Special Aircraft and Air Crew Authorization Required (SAAAR) requires dual FMS, dual GPS and dual IRU systems. PBN is increasingly possible with more aircraft equipped with FMS. The number of aircraft with FMS increased from 79% to 90% during the years 2004–09. The FAA estimated 96% of the 6653 aircraft conducting Part 121 operations in July 2011 were capable of RNAV operations with RNP 1 ([Devlin et al., 2009](#)).

Weather Integration

Severe weather has been identified as the cause of 67% of the traffic delays in the United States ([TEICAUE, 2011](#)). Weather factors such as wind, icing and visibility reduce the arrival and departure capacity at the airports. Convective weather and turbulence reduce the number of aircraft that can travel through a given airspace. Weather information is also important for imposing airspace and airport constraints ([Krozel et al., 2011](#)) in advanced planning algorithms for TFM. The NextGen Network Enabled Weather (NNEW)

will provide a single authoritative source of weather information to all the users of the NAS for enabling dynamic and collaborative planning especially during severe weather conditions by interfacing with the 4-Dimensional Weather Data Cube. The National Weather Service is primarily responsible for populating the Weather Data Cube. The Weather Data Cube will link FAA, National Oceanic and Atmospheric Administration (NOAA), Department of Defense (DOD) and commercial weather data provider databases. The system will provide the ability to convert the data between standard formats, units and coordinate systems. Finally, it will provide interfaces for retrieval of large volumes of weather data such as in a region and along the planned flight trajectory.

Data Communications

Currently, voice is the primary communications method for exchanging critical ATM information between the pilots and ground-based controllers. Communication via voice while efficient is error prone. To guard against errors, ATC communication requires read-back from the receiver, which can be time consuming especially if the read-back is incorrect. Voice communications for supporting the expected future growth of air traffic with new entrants such as Urban Air Mobility (UAM) is also not scalable because of the radio-frequency spectrum limitations. Digital data communications are less prone to errors and systems can be built with error checking and correction mechanisms. Digital data communication has the potential of improving system safety by relieving both pilots and controllers from routine tasks and enabling them to focus on strategic tasks. Increased use of digital communication in dense traffic environment will relieve radio-frequency congestion, thus freeing up voice communication for critical communications.

Data communications were first introduced in operations as a part of the Future Air Navigation System (FANS) program. FANS-1 and FANS-A developed by Boeing and Airbus, respectively, provide the ability to autonomously send some data from the aircraft to the air traffic control system using Automatic Dependent Surveillance-Contract (ADS-C) capability. The introduction of these capabilities in the oceanic airspace enabled separation distance between aircraft to be reduced from 100 to 50 nautical miles. A modified version of FANS—FANS-1/A+—that uses VHF Digital Link (VDL) mode-2 is designed for use in the higher traffic density domestic airspace. A new data communication standard harmonizing the global needs of civil aviation, Aeronautical Telecommunication Network (ATN) Baseline-2, is currently under development by ICAO (RTCA, 2013).

Operations

Some concepts and technologies for improving the efficiency in the descent, en route and surface phases of flight are discussed below.

Optimal Descent Trajectories (ODT)

ODT tools provide decision support data to air traffic controllers (Green and Vivona, 1996) for enabling continuous descents at near-idle thrust, ensuring conformance to arrival schedule constraints for maximizing throughput, avoiding traffic and airspace constraints along the arrival path and providing clearance delivery—by voice or data link—guided by knowledge of flight deck capabilities for precision guidance and control available onboard the aircraft. Different implementations of the ODT tools, Efficient Descent Advisor (EDA) (Coppenbarger et al., 2009), Continuous Descent Approach (Clarke, 2006; Ren and Clarke, 2007), and Optimal Profile Descent (Shrestha et al., 2000), have been tested in field-evaluations. These tests have demonstrated that ODT technology can save fuel and reduce emissions while avoiding conflicts with other aircraft in busy terminal areas (Shrestha et al., 2000).

The feasibility of use of three-dimensional trajectory clearances issued over data link for automated guidance and control using onboard flight management system was evaluated in Tailored Arrivals (TA) to San Francisco operational trials. Tests of this NASA developed technology were conducted by a partnership between FAA, Boeing and United Airlines during 2006 and 2007. Boeing estimated use of the TA process could save between 400 to 800 pounds of fuel per arrival. In 2012, NASA transferred the results of the research for defining and validating the EDA concept to the FAA for further evaluation, development and operational use as a part of NextGen technologies.

Wind-Optimal and User-Preferred Routes

Airlines operations are focused on reducing the cost during cruise—considering cost of fuel and crew time—because most of the time is spent and fuel is consumed in the cruise phase. In the current system, aircraft cruise at a fixed altitude and airspeed along the planned horizontal route from origin to destination. The optimal route, cruise altitude and cruise speed are amended to comply with terminal area and en route restrictions due to airport and airspace capacity constraints and for circumventing regions of severe weather. Flying this non-optimal trajectory results in higher fuel consumption and greater emissions. A study using air traffic data covering flights to/from the top 34 airports in the continental United States during 2007 estimated the routes used by aircraft were 2.9% longer than the direct routes between the city-pairs. The corresponding distance for traffic between the top 34 city-pairs in Europe was 4% longer (Ren and Clarke, 2007). The extra distance traveled over great-circle routes is significantly greater over US-Europe oceanic airspace because of reliance on procedural separation due to the lack of radar surveillance and VHF radio communication coverage. This could change with more aircraft equipped with the ADS-B system. Flights from Europe to Asia need to fly longer routes due to large amount of restricted airspace, strict entry points and steep terrain. Several studies have determined the limitations of the current routing structure and estimated the benefits of using wind-optimal routes (Hewell et al., 2003;

Reynolds, 2008; Kettunen 2005). Even though wind optimal routes are longer compared to direct routes, the direct operating cost is reduced by taking advantage of the winds.

Surface

Airport Surface Detection Equipment–Model X (ASDE-X) deployed at 35 major U.S. airports provides position information for tracking the movement of aircraft and vehicles on the airport surface. ASDE-X acquires data using radar, multilateration and ADS-B. The acquired data are provided to systems used by ramp operators, air traffic controllers, traffic managers, flight operators and aviation system managers for managing surface traffic movement—scheduling gate departure, predicting conflicts and runway entry times, preventing runway incursions, resolving conflicts, determining taxi route and schedule compliance—and evaluating airport performance—delay and throughput metrics and causal factors. Data sharing promotes common situational awareness and collaborative decision-making for enhancing safety and traffic flow on runways, taxiways and in ramp areas. These data are also important for airport incident and accident investigations. In addition to ASDE-X at 35 airports, the FAA plans call for deployment of Airport Surface Surveillance Capability (ASSC), a multilateration and ADS-B based system, at additional nine busy airports—Portland International (PDX), Ted Stevens Anchorage International (ANC), Kansas City International (MCI), Louis Armstrong New Orleans International (MSY), Pittsburgh International (PIT), San Francisco International (SFO), Cincinnati/Northern Kentucky International (CVG), Cleveland Hopkins International (CLE) and Andrews Field (ADW). ASSC tracks transponder-equipped aircraft and ADS-B-equipped ground vehicles on the surface and aircraft flying within five nautical miles (nm) of airports. Surface data acquired by these systems are also provided in the SWIM feed to the different stakeholders. SWIM is the NextGen's digital data-sharing backbone. SWIM Terminal Data Distribution System (STDDS) processes the raw surface and terminal surveillance data and sends surface information from airport towers to the corresponding TRACON facility through NAS Enterprise Messaging Service (NEMS) for internal and external NAS users (RTCA, 2013).

Integrated Technology

NASA and FAA are collaborating to develop and demonstrate an integrated set of NextGen technologies (Jung et al., 2013) that provide an efficient arrival solution for managing aircraft beginning from just prior to the top-of-descent and continuing down to the runway. These technologies are: ADS-B, RNAV arrival routes, Optimized Profile Descent (OPD) Procedures, Terminal Metering, Flight Deck Interval Management (FIM) and Controller Managed Spacing (CMS) tools. NASA and the FAA have demonstrated the feasibility of sustained high throughput of fuel-efficient arrival operations using precision time-based scheduling which provides runway arrival times and fix crossing times for arriving aircraft. Aircraft are delivered to meter fixes according to schedule, but with small spacing errors that need to be reduced to maximize throughput and avoid spacing violations. Most flight crews use FMS to fly OPDs along RNAV/RNP routes—largely without controller intervention. Terminal controllers correct residual spacing errors and cope with disturbances and off-nominal events using tools and display enhancements based on 4D trajectories. The integration of these technologies and the associated tools will enable aircraft to fly closer together on more fuel-efficient routes, thereby providing even greater benefits in terms of increased capacity and reduced delay, fuel burn, noise and greenhouse gas emissions.

Global Harmonization

The FAA works with other international Air Navigation Service Providers (ANSP) to ensure the interoperability of technologies developed in the U.S. and in other countries under the auspices of the ICAO to enable equipped aircraft to operate globally. Collaboration with the Single European Sky Air Traffic Management Research (SESAR) continues to play an important role in coordinating research and technology development in the U.S. and Europe.

The Asia and Pacific Initiative to Reduce Emissions (ASPIRE) (Aspire, 2000) is a collaboration between the FAA and ANSPs in Australia, New Zealand, Singapore, Japan and Thailand. ASPIRE conducted a series of flights in 2008–11 to successfully demonstrate the potential for fuel and emissions savings in the region. These flights employed modified gate-to-gate operations, including reduced separation, more efficient flight profiles and tailored arrivals. The best practices from these tests can be applied to flights—with properly equipped aircraft—between some cities in the United States and in the Asia Pacific region.

During 2011, the FAA, the European Commission, several European ANSPs and 40 European airlines participated in the demonstration of NextGen and SESAR capabilities on transatlantic flights. As a participant of the Atlantic Interoperability Initiative to Reduce Emissions (AIRE) (Aspire, 2000; AIRE, 2007), Air France flew several flights between John F. Kennedy International (JFK) and Paris Charles De Gaulle (CDG) as well as between Paris Orly (ORY) and Guadeloupe's Pointe-a-Pitre Airport (PTP) during 2010–11. The flights procedures were designed to reduce environmental impact without special equipment. Various improvements to taxiing, real-time lateral and vertical optimization and fuel saving RNAV approaches produced fuel savings ranging from 200 to 300 gallons per flight. Global harmonization must allow for the evolution of aviation systems around the world in a way that allows ANSPs and Airspace Users to invest in advanced capabilities.

The harmonization work should identify key components that will guide prototype testing, functionality, and prioritizing implementation efforts to solve the roadblocks to global interoperability. ICAO has defined standards for global interoperability. Aviation System Block Upgrade capabilities (Lutte, 2015) facilitate strategic planning and investment decisions with a goal of global aviation system interoperability. Initiatives around the world, like NextGen and SESAR, are addressing their own local or regional issues with initiatives to work together.

Newly Emerging Technologies

Unmanned Aerial System Traffic Management

Many beneficial civilian applications of small UAS weighing less than 20 kg have been proposed. Applications include package delivery, infrastructure surveillance, monitoring for search and rescue and agricultural inspection. An established infrastructure for enabling and safely managing widespread UAS operations in low-altitude airspace doesn't exist at present. A UTM system that is being envisioned now is expected to make extensive use of automation for reducing the cost of such operations. The vehicles are also expected to be largely autonomous. It will be difficult for human operators to monitor every vehicle continuously, therefore, automation will be needed for ensuring that these vehicles stay separated from each other and from commercial and general aviation aircraft. The automated system will also need to provide information to humans for making strategic decisions for fleet management and flow management driven by demand, capacity and wind and weather conditions.

NASA in collaboration with the FAA, industry and academic partners has conducted a series of increasingly complex flight tests to develop requirements for the UTM system. The first field test conducted in August 2015 was focused on UAS operations for agriculture, firefighting and infrastructure monitoring. It enabled UAS operators to file flight plans reserving airspace for the duration of each flight. This spatiotemporal reservation was employed for separation assurance by preventing other flights from entering the same airspace segment at the same time. The second field test in October 2016 demonstrated beyond visual line-of-sight flight in sparsely populated areas. It examined technologies for dynamic adjustments based on availability of airspace and contingency management. The third field test in May 2018 examined capabilities for tracking cooperative and uncooperative UAS flights over moderately populated areas. This ability to track is essential for keeping the manned aircraft separated from the unmanned aircraft and vice-versa. The final—fourth—field test during May–August 2019 focused on UAS operations in higher-density urban areas for tasks such as news gathering and package delivery. These activities also tested technologies that could be used to manage large-scale contingencies. NASA's research on UTM has established the innovative concept that various navigational and planning functions will be provided as services by distributed entities. NASA provided results from these tests in the form of airspace integration requirements to the FAA in 2019 for maturing UTM.

Urban Air Mobility (UAM)

Road transportation was the mode of transportation for short distances in the 20th century and air transportation for distances greater than 500 miles (Schafer, 2000). The development of Short/Vertical Takeoff and Landing (S/VTOL) aircraft in the 1970s was unsuccessful in gaining broad acceptance due to noise and ride comfort issues (Fry and Zabinsky, 1967). Helicopters remained special purpose vehicles for use in emergency situations, firefighting and applications where fixed wing aircraft could not be operated due to terrain and space limitations. This model is changing with advances in light-weight composite materials, electric propulsion (including distributed electric and hybrid—gas-electric) and battery technology. These technologies have enabled construction of commercial Electric VTOL (eVTOL) aircraft for carrying one to six persons that promise unprecedented growth for moving people in urban metropolitan areas with the potential for decreasing road traffic congestion. Advances in cloud computing, data science, open source software and satellite technology can be expected to make UAM operation feasible, efficient and cost effective.

The actual growth, however, will depend on the public perception of the noise and visual scene of hundreds of aircraft flying at low altitude in densely populated areas in addition to the economics of operations. A recent market study for NASA (Goyal, 2019) considered the demand and barriers for Airport Shuttle, Air Taxi and Air Ambulance. This study concluded Air Ambulance is currently not viable using eVTOL. While it valued the Air Taxi and Air Ambulance market at \$250 billion, the available market size was reduced to \$2.5 billion based on overcoming legal/regulatory, certification, public perception and weather constraint challenges.

The UTM and UAM systems must provide all the services—safe separation between aircraft, resolution of conflicts and efficient path planning—enjoyed by traditional air traffic at a fraction of the cost. The ability to model and predict winds at low altitudes presents a challenge for low altitude flights especially for safety of power-limited smaller vehicles. These systems also need to be effectively integrated with the traditional ATC and TFM decision support systems for a seamless air transportation system.

The current vision of UAM, like UTM, is a community-based, collaborative traffic management system with operators coordinating, managing and executing operations within the established legal framework. The UAM system will provide federated services for enabling collaborative management of operations between UAM-vehicle fleet operators, supported by their service suppliers, exchanging information digitally using data-communication networks. In addition to the wired data-communication networks, data will be exchanged wirelessly—using airband radio and satellite communication—between the UAM-vehicles and between UAM-vehicles and ground-based systems. This cyber-physical world of interconnected and interdependent systems increases the vulnerability of aircraft and air traffic management systems to cyberattacks. The impact of security breaches includes potential of both economic harm and loss of life.

Some of the cyber-physical system challenges highlighted by the aviation community are: (1) security and authentication for guarding against malicious activities and for preventing unlawful access to operator and government systems, (2) information/data integrity for ensuring information and data are conforming and trusted, and (3) data access for providing data to law enforcement, state and federal authorities enabled using remote ID information and correlation. Future information management system designs need to leverage International Aviation Trust Framework (IATF) framework and policies.

Unmanned Aircraft Systems

Unmanned Aircraft Systems (UAS) such as General Atomics Predator and Reaper drones and the Northrop Grumman Global Hawk drone are longer and have a greater wingspan compared to a Cessna 172. Global Hawk is about half the length of a Boeing 737 and has a greater wingspan. These aircraft can fly at high altitudes where commercial jet aircraft fly. While these aircraft are well equipped with sensors and largely autonomous, they are remotely piloted. Due to this reason, these aircraft are also called Remotely Piloted Vehicles (RPV). Because flying these vehicles on-demand by the military is disruptive to the scheduled commercial flights, coordination with the civilian air traffic system is needed. In the past several years, the FAA, DOD and NASA have been developing technologies for integrating UAS operations in the NAS. One of the critical enabling technologies for successful integration is Detect and Avoid (DAA) system.

DAA systems provide surveillance information, alerts and maneuver commands to pilots for keeping their aircraft separated—well clear—from other aircraft (Cook et al., 2015). The data needed for defining DAA Well Clear (Cool et al., 2015; Goyal, 2019) (DWC) and performance requirements for alerting and maneuvers have been derived from flight tests and simulations. References 64 and 65 describe prototype DAA methods. RTCA Special Committee 228 (SC-228) published the Phase 1 Minimum Operational Performance Standards (MOPS) for DAA systems (Johnson et al., 1993) and air-to-air radar (Cook et al., 2015) in 2017 based on the outcome of research. The FAA published the corresponding Technical Standard Orders (TSO): TSO-C211 and TSO-C212 in October 2017. Phase 1 MOPS are for operations outside the terminal areas. These MOPS suggest combinations of radar, ADS-B and Tra-c Alert and Collision Avoidance System (TCAS) II technologies. The major objective for Phase 2 MOPS is defining requirements for low cost, size, weight, and power (low C-SWaP) sensors for use by slower UAS aircraft—speed less than 200 knots. The challenge of low C-SWaP sensors is they must provide adequate surveillance volume and accuracy for the DAA system. An additional objective of Phase 2 is DWC while conflicting with aircraft without a functioning transponder. Because Phase 1 permits use of TCAS II, DWC was defined to enclose the TCAS alerting volume to prevent TCAS advisories from triggering. TCAS II advisories cannot be triggered in encounters with aircraft without transponders, therefore, the DWC volume can be reduced for such encounters. Reference 68 presents analysis of the surveillance volume effect on DAA alerting performance for SC-228 Phase 2 MOPS development. Surveillance volume is important for providing enough time for UAS pilots to maneuver according to DAA advisory. While additional surveillance volume benefits the DAA system performance, the sensor cost, size, weight and power increase beyond an extent makes it impractical.

Conclusions

This article begins with the description of the air traffic management system in the United States in which the pilots, controllers and dispatchers interact with each other to ensure safe and efficient air traffic operations. The U.S. airspace was described as organized in 24 regions with 20 Air Route Traffic Control Centers in the continental United States, one in Anchorage and three Combined Center and Radar Approach Controls in Honolulu, Guam and San Juan, respectively. The two main functions of traditional air traffic management, separation assurance and traffic flow management were discussed. The essential steps of trajectory-based separation assurance, trajectory prediction, conflict detection and conflict resolution were described. Traffic Flow Management was described in terms of national traffic flow management and regional traffic flow management. Next, terminal area operations and surface operations were briefly described. Several advanced airspace operations concepts being pursued by the Federal Aviation Administration, National Aeronautics and Space Administration and industry for better data sharing and decisions across decision support tools were highlighted. These included Integrated Demand Management, Integrated Arrival, Departure and Surface Metroplex Traffic Management, Applied Traffic Flow Management and Environmentally Friendly Operations. The NextGen portfolio of projects in various stages of implementation noted in the article included Automatic Dependent Surveillance-Broadcast, Performance-Based Navigation, weather integration, data communications, integrated technologies and global harmonization. Technical challenges and emerging technologies related to Unmanned Aerial System Traffic Management, Urban Air Mobility and large Unmanned Aircraft System for the future air traffic management system were outlined. The major challenge for the U.S. air traffic management system in the future will be safely accommodating the operations of new types of aircraft including electric vertical takeoff and landing aircraft for applications such as mobility of people and cargo in the urban areas. Other challenges will be increased use of automation in the vehicles and systems for managing air traffic, role of humans in highly automated environment and greater role of aircraft operators in the safety and efficiency of operations.

Acknowledgments

The authors are grateful for several NASA colleagues for reviewing the paper and providing feedback for improving the manuscript.

Glossary

Airspace Users (AU) Civil aircraft operators (including airlines, charter flights, cargo flights, general aviation), military operators, hot air balloon operators, and unmanned aerial vehicle operators.

Air Traffic Control (ATC) Service provided by an air traffic controller in which the aircraft receives a series of instructions to ensure a *safe, orderly, and expeditious* flow of traffic. ATC Includes the service provided by air traffic controllers in the Tower during take-off and landing, approach control during climb and descent, and area control center during the en-route phase of flight.

Air Traffic Controller (ATCO) Professional responsible for providing air traffic services to all aircraft in the airspace under their control.

Air Traffic Flow Management (ATFM) Set of ATFM measures applied tactically when a demand/capacity imbalance takes place. The main goal of these measures is to reduce demand temporarily to meet the reduced capacity.

Air Traffic Management (ATM) A broad term that includes Air Traffic Services (ATS), Air Traffic Flow and Capacity Management (ATFCM), and Airspace Management.

Air Traffic Services (ATS) All services provided to an aircraft during the flight, including Air Traffic Control (ATC), Flight Information Service (FIS), and Alert Service.

Area Navigation (RNAV) Navigation method composed of a series of ground or space-based stations to allow navigation in any desired course within the coverage area of the stations.

ATC sectors Portions of airspace where an ATCO is responsible for providing air traffic services.

Distance Measuring Equipment (DME) Ground-based navigation device used for distance measuring between the aircraft and the transmitter.

Flow Management Positions (FMP) Cell located in ATC facilities responsible for connecting the local ATC needs with network manager instructions.

International Civil Aviation Organization (ICAO) United Nations agency created in 1944 to regulate the international civil aviation.

Network Manager Central organization responsible for ATFCM and coordinating the application of flow control measures in a country or set of countries.

NOTAM Notice to airmen used to alert pilots of any aeronautical information that might affect the safety, regularity, or efficiency of the flight.

Very High Frequency Omnidirectional Range (VOR) Ground-based navigation device that emits radio beacons which are interpreted by the receiving equipment onboard, allowing an aircraft to determine its relative position to the transmitter.

Air traffic has been increasing in the past years, and the predictions indicate a more significant growth in the future. On the other side, the infrastructure required to provide a safe, orderly, and expeditious flow of traffic does not grow as fast because it is costly. The high price tag encourages the authorities to make sure the existing infrastructure is optimized as much as possible before making any investment to increase capacity. Air Traffic Flow and Capacity Management (ATFCM) is part of Air Traffic Management (ATM) that seeks to balance the increasing demand with a limited capacity (Cinar and Demirel, 2017).

Demand and capacity are on opposite ends of the scale, but proper management of both is a necessary step to provide a quality service for all airspace users.

Capacity Management

To correctly manage the airspace capacity, it is paramount to have an in-depth knowledge of the existing capacity of airports and air traffic control facilities. It is also essential to know the limitations involved in the expansion of this capacity to cope with the rise of demand.

The ideal scenario would be real-time monitoring of the existing capacity and current demand where the capacity could be increased quickly whenever necessary. In the real world, this expansion of airspace and airport capacity is not so simple.

Airspace Capacity Assessment

Many factors can affect the capacity of an Air Traffic Control sector (ICAO, 2005a).

When assessing capacity values, factors to be taken into account should include:

1. the type of Air Traffic Services (ATS) provided,
2. the complexity of the control sector or the aerodrome concerned,
3. controller workload as measured by the capacity assessment team, including control and coordination tasks to be performed,
4. the types of communications, navigation and surveillance systems in use, their degree of technical reliability and availability as well as the existence of backup systems, and
5. existence of ATC systems providing controller support and alert functions.

The most crucial factor which determines the capacity of an ATC sector is the air traffic controller workload (Majumdar and Ochieng, 2002). Therefore the capacity of a given sector is a measure of all factors which affect the mental and physical activities of the air traffic controller. The goal is to keep the workload below an acceptable level where safety is not jeopardized.

The methods for measuring controller workload are usually categorized as subjective or objective. Subjective self-assessment of controllers is carried out either by instantaneous techniques or non-instantaneous techniques. Objective methods involve direct observation of controllers, usually by other controllers or ATC system experts.

Although a lot of effort has been made to define and measure the workload of an air traffic controller, there is not yet one definitive method to assess the airspace capacity based on the air traffic controller workload. The primary concern is transferability, as the techniques developed for the specific scenario of a country can hardly be applied directly on other countries (Majumdar et al., 2005).

Airspace capacity can be improved in the long term by redesigning the airspace to create optimized routes that will accommodate more aircraft without increasing the ATCO workload. In the short term, better management of the working positions is enough to alleviate the burden on overloaded sectors.

Working Positions Management

The amount of aircraft being serviced by an air traffic controller on a given sector plays a significant role in the workload of the Air Traffic Controller (ATCO). The management of working positions might be enough to reduce the workload and consequently increase the capacity of a portion of the airspace.

Figure 1 Dynamic sector boundaries can help reduce the workload of some sectors. (A) Before dynamic airspace configuration. (B) After applying dynamic airspace configuration.

It is a common practice in ATC facilities to group two or more sectors when the demand is low. Once the demand starts to rise, the ATCO can monitor the workload of the ATCOs and ungroup the sectors as a tactical solution to increase the airspace capacity. In some cases, a specific sector is only ungrouped if the demand is expected to reach a peak due to some unusual circumstances.

ATC sectors traditionally have well defined boundaries. But some recent research suggests (Martinez et al., 2007; Zelinski and Lai, 2011) that dynamic sector configuration according to the evolution of traffic gives better results on smoothing out of peaks of demand and results in a higher capacity. Fig. 1 shows an example of how the dynamic changing of boundaries can reduce the workload on some sectors. On Fig. 1A, sector 1 is overloaded while sector 2 has available capacity. Fig. 1B shows the result of dynamic sectorization, where all sectors have similar workloads.

Flexible Use of Airspace

Airspace is a limited resource and the consensus states that certain portions of the airspace should not be restricted to a single type of use.

The key to avoiding unnecessary reduction of the airspace capacity is to limit the duration of the restrictions on a portion of the airspace only for the period in which they are required.

Restricted airspaces are portions of the airspace wherein activities must be confined because of their nature, or wherein limitations are imposed upon aircraft operations that are not a part of those activities, or both. Permanently restricted airspaces are depicted on aeronautical charts, while temporarily restricted airspace is published via NOTAM. Fig. 2 shows an example of a restricted area published on an aeronautical chart.

There are three main types of restricted airspace:

Figure 2 Restricted area 2935 used for rocket launches at Cape Canaveral.

- Danger area: An airspace within which activities dangerous to the flight of aircraft may exist at specified times.
- Prohibited area: An airspace above the land areas or territorial waters of a State within which the flight of aircraft is prohibited.
- Restricted area: An airspace above the land areas or territorial waters of a State, within which the flight of aircraft is restricted following certain specified conditions (ICAO, 2005a).

Flexible use of airspace (FUA) is a concept that allows restricted airspace to be activated when necessary and makes that same airspace available for the use by all aircraft for the rest of the time.

Airport Capacity Assessment

The capacity of an airport can be divided into two main domains, namely the airside and the landside. The airside capacity includes the Terminal Manoeuvring Area (TMA) approach and departure interface, the runways, the taxiway configuration and aprons up until the gates. The landside capacity involves everything that happens after a passenger leaves the plane, including terminal structure, baggage handling, and transportation links to and from the airport. Fig. 3 depicts the airside and landside separation present in most airports. Delays can also be caused by systemic processes that affect landside capacity but they are out of the scope of this work (O'Flynn, 2016).

The airside capacity assessment can be viewed as the maximum sustainable throughput of a runway system which, in practice answers the question, "How many aircraft operations can an airfield reasonably accommodate in a given period of time when there is a continuous demand for service during that period?" (Fisher, 2012).

Airport capacity enhancement usually starts with an efficiency assessment. If demand continues to surpass the capacity regularly and the systems are already operating at maximum efficiency, the solution to increase capacity will be the construction of new and more efficient infrastructure.

Figure 3 Areas that affect airside capacity and landside capacity.

Air Traffic Flow Management

Airspace capacity can't always be increased as fast as it would be desirable. Since capacity can't always be increased, Air Traffic Flow Management (ATFM) has been long recognized as a principal instrument to deal with capacity shortfalls and delay phenomena in the transportation system (Madas and Zografos, 2008).

The problem is to determine how to optimally control aircraft by rerouting, delaying, or adjusting the speed of the aircraft in the air traffic control system to avoid airspace regions that have reduced capacities. The overall objective is the minimization of delay costs that include all applicable fuel costs, safety costs, and taxes (Bertsimas and Patterson, 2000).

ATFM Measures

A variety of tools are available to help modulate the demand. Each ATFM measure can be used alone or in combination with other measures. The most common ATFM measures are described further. Fig. 4 shows the decision flow usually followed when applying ATFM measures.

Figure 4 Decision flowchart for ATFM measures that will be applied according to the situation.

Slots

Slots are used by the airport administration to allocate a specific time window for an aircraft to take-off or land. When slots are applied, the airport is considered as a coordinated airport. Aviation is the most global of industries. Where capacity constraints exist, the guidelines should be uniform around the world. These guidelines are published by the International Air Transport Association (IATA).

Coordination is the allocation of constrained or limited airport capacity to aircraft operators to ensure a viable airport and air transport operation. Coordination seeks to maximize the efficient use of airport infrastructure. It is not a solution to the fundamental problem of a lack of airport capacity. In all instances, coordination should be seen as an interim solution to manage congested infrastructure until the long term solution of expanding airport capacity is implemented (IATA, 2017).

Miles-In-Trail

One way to impose restriction criteria on a stream of aircraft approaching the same airport, to a specific sector or a portion of airspace is to determine a minimum distance that will be acceptable between two aircraft. This type of ATFM measure is known as miles-in-trail (MIT). It requires the transferring ATCO to use other measures to obtain the desired separation. For example, speed restriction, holding pattern, or vectoring.

Research around this topic include the development of an MIT Impact Assessment Capability that could allow a flow manager to tailor each MIT, accurately setting start time, stop time, spacing value, and thus the affected flight set (Ostwald et al., 2006).

Minutes-In-Trail

Instead of requesting a specific distance between two consecutive aircraft, the receiving sector might require a specific time spacing over the sector boundaries.

This ATFM measure is called Minutes-in-trail (MINIT). It can be used when the receiving sector is not capable to provide RADAR surveillance. MINIT is very similar to the MIT as both are considered flow-rate limits but the latter is usually applied when there is a need for a lower flow.

Rerouting

When the weather conditions are poor, the capacities of some airports and ATC sectors drop significantly. Depending on the conditions the capacity can be reduced to zero. Aircraft must then fly alternative routes if they were scheduled to pass through airspace regions of reduced capacity (Bertsimas and Patterson, 2000). This enables the use of airspace capacity that is not fully used at the moment and relieves the burden on an overloaded sector. The challenge is to define a new route that is far enough from the original one to alleviate the sector that is facing a temporary peak of demand without increasing too much the time and cost of the new route.

Aircraft usually depart with a predefined route that is programmed to be flown if nothing unexpected happens. This route is declared in the flight plan and can be cleared as proposed or changed by the ATC before departure. The complexity of the problem of rerouting often requires the use of decision support tools (DST) to provide a better solution than the one given by the human operators. For example, a linear integer-programming model to support strategic ATFM decisions related to ground delays and dynamic rerouting of flights proposed by Mukherjee and Hansen (2009) has resulted in 10%–15% delay cost reduction compared to static rerouting. This model also achieved about 50% less delay cost compared to a pure ground holding strategy.

Ground Delay

The use of ground delays sometimes is also referred to as Ground Delay Program (GDP). The Network Manager (NM) issues GDPs whenever it expects sustained periods of congestion at an airport. Usually, this is caused by a sudden decline in the destination airport arrival capacity due to adverse weather conditions. In a GDP, flights that are scheduled to arrive during the expected periods of congestion are assigned delays before their departure, hence, the term ground delay. The reason is that it is both safer and less expensive to delay a flight on the ground (i.e., before its take-off) than to delay an airborne flight (Vossen and Ball, 2006). If the capacity drops even further or if it stays lower for long periods, the GDP might evolve to a Ground Stop Program (GSP), where all aircraft destined to one airport are not allowed to take off until the capacity is restored.

GDP is a tactical measure, therefore the decision to use it is made mostly on the day of the operation. Slots are similar to GDP but they are used as a strategic measure since one airport becomes coordinated only due to circumstances that are foreseen months before the operation.

The simplest form of implementing GDP is by establishing a fix distance or time between two aircraft heading to the same destination, also known as Minimum Departure Interval (MDI). The use of MDI doesn't require any decision support tools since it relies solely on the expertise of the ATCO. But there are very sophisticated algorithms being developed that aim to improve the results of GDP. One example is the Dynamic Stochastic Ground Holding (DSGH) algorithm that dynamically adapts to weather forecasts by revising, if necessary, departure delays (Mukherjee et al., 2012).

Linear Holding

Linear holding (LH) can be seen as a postponing of the delay that would be applied on the ground as a part of a GDP. The aircraft is allowed to take off a few minutes earlier but has to fly at a slower speed. The advantage over ground holding is that once the aircraft is airborne, the speed can be adjusted dynamically within a specific range if the conditions change during the flight. For this reason,

Figure 5 Ground delay can be applied before take-off. Linear holding can be applied for the whole flight. Holding pattern can be applied as long as the aircraft has enough fuel.

linear holding can be considered more flexible when compared to a ground hold. LH also has some advantages when compared to conventional airborne holding.

Typical airborne holding would consume more fuel due to the extended flight track (assuming no specific speed adjustment), while ground holding has no impact on fuel consumption in most cases. Due to the increased extra fuel, the airborne holding time is fairly limited, taking account that safety-related issues may arise from a reduction of the on-board reserve fuel (Xu and Prats, 2017).

Holding Pattern

Conventional Holding Pattern (HP) is used to maintain the aircraft in a specified space while the adjacent sector or the destination airport has a limitation in capacity. It is probably the oldest of the ATFM measures.

Every holding pattern is designed with a fix that will define the beginning of the holding. It can be a navigational aid like a VOR, a DME distance or an RNAV fix.

The speed used during the holding pattern is usually lower than the speed used during the cruise phase of the flight to decrease the turn radius and the size of the airspace occupied (ICAO, 2016).

Corrections for wind in the heading and timing can be applied to maintain the holding pattern as specified. These corrections usually are performed by the aircraft FMS automatically.

A holding pattern is not the most efficient ATFM measure but sometimes it is the last resort available to ATCOs.

Ground delay, linear holding, and holding pattern have similar effects, but the moment of application and the flexibility are slightly different. Fig. 5 shows where these ATFM measures can be applied.

Diversions

Diversions are not considered ATFM measures but are included here just for completeness, as they can be used in extreme cases when the capacity of the destination airport drops severely and unexpectedly.

There can be many causes for this sudden drop in capacity, like a damaged aircraft on the runway, unserviceable navigational aids or adverse weather conditions. If the estimated time for restoring the capacity of the airport is greater than the time available for holding according to the fuel of the aircraft, the flight is diverted to an alternate airport. This is very costly for the airline company and brings a lot of inconvenience to the passengers. Therefore a diversion is used only when there is no other option available.

List of Flights Exempted From Flow Control Measures

The International Civil Aviation Organization (ICAO) determines that the following types of flights should be granted exemption from flow control measures (ICAO, 1984):

- flights in a state of emergency, including flights subjected to unlawful interference,
- flights operating for humanitarian reasons,
- medical flights specifically declared by medical authorities,
- flights on search and rescue missions,
- flights with "Head of State" status, and
- other flights as specifically required by state authorities.

Phases

On a time scale, Air Traffic Flow Management (ATFM) can be divided into four phases. Firstly, the strategic phase deals with questions that require a change in infrastructure to be solved. The pre-tactical phase prepares the final adjustments for the day of the operations when the tactical phase is carried out. After the operation, the data collected is analyzed on the post-operational analysis. Fig. 6 resumes the moment of each phase and the actions that are taken (ICAO, 2005b).

Figure 6 Phases of ATFM and the actions taken on each phase.

Strategic

The strategic phase of the flow management comprises the period seven days or more prior to the day of a specific operation. During this phase data are collected in order to detect any major imbalance between ATC capacity and the foreseen demand. Seasonal or significant events like national holidays are examples of a possible cause of a spike in demand. Military operations, significant weather conditions, or construction work in key airports could be responsible for a drop in demand. If such imbalance is detected, the measures taken to reestablish the balance can include: optimization of the existing capacity, use of other available capacities and demand regulation.

Pre-Tactical

The pre-tactical phase of the flow management takes place between 6 days and 1 day before the operation. It consists of a fine-tuning upon the planning that was prepared during the strategic phase. Based on the outcome of the ATFM measures taken on the strategic phase and the updated information about capacity and demand, corrections are made and some of the possible tactical ATFM measures are prepared.

Tactical

On the day of the operation, the NM and the Flow Management Positions (FMPs) carefully monitor the evolution of the traffic in a timely manner. Special attention is given to those sectors or moments in which the capacity is going to be reduced or the demand is expected to rise. If necessary, new restrictions are applied.

Post-Operational

During the previous phases, data are collected in order to allow a post-operational analysis of the actions.

This is a cyclic process and the outcome of one iteration is used to improve the actions taken on the next one. This is important to correct mistakes and to consolidate good practices.

CDM

Many complex processes require the cooperation of multiple parts to function properly. The outcome of these processes can be improved if each stakeholder is allowed take part on important decisions.

The ATFM is one of these complex systems which require different parts working together synchronously to produce the desired effect. The decisions taken for a specific flight or a group of flights have huge impacts for every party involved. In this context, the Collaborative Decision-Making (CDM) is applied whenever possible in ATFCM.

CDM embodies a new philosophy for managing air traffic. It is based on the belief that air traffic flow management can be improved if there is a closer collaboration between the stakeholders, including the Network Manager (NM), the Flow Management Positions (FMPs), and the airspace users (AUs) with large benefits for all parties. This collaboration takes the form of mutual exchange of data and more flexible and efficient collaborative procedures (Ball and Lulli, 2004).

The Future of ATFCM

One of the most promising technologies for the future of ATM is four-dimensional trajectory based operation (4D TBO). This concept allows a precise description of an aircraft's path in space and time during the whole flight. Conflict detection and resolution

Figure 7 4D trajectory based operations programs of each country/region.

will be possible even before the aircraft starts the engines, reducing congestion in airspace and the workload of Air Traffic Controllers (Ayhan et al. 2018; Ribeiro et al., 2018). Trajectory prediction will be more precise because the onboard Flight Management System (FMS) will receive updated information about wind and temperature available for the intended route (Legrand et al. 2019).

Many countries/regions are developing or starting the implementation of their own 4D TBO programs like Next Generation Air Transportation System (NextGen) in the United States, Single European Sky ATM Research (SESAR) in Europe, Collaborative Action for Renovation of Air Transport Systems (CARATS) in Japan, Sirius in Brazil and Future Indian Air Navigation System (FIANS) in India. Fig. 7 shows a map of the countries and their respective programs. Once 4D TBO is fully implemented, it will have a huge potential to entirely extinguish delays or providing optimal solutions in the cases where ATFM measures have to be applied.

The CDM is going to be much more efficient in the future as the System Wide Information Management (SWIM) comes into practice. This effective information management and sharing enables each participant to be aware of information of relevance to other participants' decisions (ICAO, 2018).

Port Management: An Overview

Port management is defined as the strategic decision making, and the subsequent monitoring and controlling of ports and terminals. It encompasses the management of port facilities, including infrastructures, superstructures, and substructures, which may be privately or publicly owned. Ports serve a significant role in the global economy, trade, transport, but also global and national security: Their role is to facilitate the global flows of trade and passengers, thus promoting the economy. They help global and national security by safeguarding our borders, and thus prevent illegitimate activities (Burns, 2014a).

Ports are the convergence points of supply chains that facilitate ships' loading and unloading operations, but also offer them a safe shelter during adverse circumstances, for example, extreme weather conditions, etc. They are the nodal points that facilitate the global movement of people and cargoes.

Throughout the history of humankind, ports have been reflecting the level of economic prosperity, technological innovation, and progress. Developed economies demonstrate their dominance by expanding seaports. In fact, the rise and fall of economic empires can be predicted by observing the growth of national seaports, and trade activities.

The Significance of Maritime Trade

Although global transportation consists of multimodal nodal points (i.e., ports for sea, land, and air), seaports hold a prominent position for many reasons. First, they represent about 80% of global trade and transport. At a global level, there are about 9,000 large and medium sized global ports, and about 100,000 ships, among which about 50% are ocean-going (i.e., 3,000 deadweight or larger), and 50% are smaller ships involved in short-sea shipping. Second, two-thirds of planet earth are covered by water. Third, the ship size is much larger compared to the land and air transportation modes: the length of modern ships is comparable to the height of the Empire State building, that is, exceeding 1,000 feet. The volume of cargoes a large ship can carry, could fit in over 230 Olympic swimming pools. Fourth, maritime trade is the most cost effective transportation mode; the longer the voyage, the lower the cost per unit is, since ships benefit greatly from economies of scale (Burns, 2014b).

The global maritime industry is highly competitive, and therefore port management requires a multitude of skills for the management of different departments and tasks, encompassing all executive and operational activities. Port managers need to employ all the factors of production including labor, land, capital, and everything that capital can buy: immobile assets such as new terminals, mobile assets, such as technologies, etc. High-level port management entails strategic decision making regarding the market needs, competition, investment, and others.

Port Management Encompasses Strategy and Operations

In our modern, fast paced global supply chains, port managers have become a hybrid of strategists and operators, due to the increasingly industry, with a plethora of critical decisions that need to be made. As seen in Fig. 1, port managers are in charge of business development and investment decisions such as port expansion, etc. They negotiate contracts oversee concession agreements between industry stakeholders and port authorities. They are in charge of asset management, and thus select banking institutions and financing terms and conditions. They decide to which extent the port should invest in new terminals and new storage areas. They are responsible for asset management, port operations, cargo loading and discharging, cargo handling, etc. They conduct cost and

Figure 1 Port management strategy and operations. *Source: By Prof. Maria Burns.*

Figure 2 Port ownership models from public service to full privatization. *Source: By Prof. Maria Burns.*

benefit analyses to decide how much dredging is enough (i.e., the deepening and widening of the sea bottom, by removing debris and sediments). They must decide on the port's level of automation, while training their personnel, to upgrade their skills. They need to recruit, train, and supervise thousands of port workers, such as stevedores (longshoremen), terminal operators, engineers, crane operators, maintenance and repair teams, cyber and physical security professionals, transportation planners, and various other specialists (Burns, 2015).

Port Ownership Styles

Port ownership involves decisions on the land, infrastructure, superstructures, and substructures, and any management and operational activity involving the terminals, cargo handling equipment, and various other services.

Until the 1960s, government-centric strategies and management decisions about ports. After the 1960s, especially due to the globalization, port decisions were made at a state level, as only the local authorities had a better understanding of the strength, weaknesses, challenges, and opportunities. Gradually, the control at a public level was shifted with the public sector becoming more prominent.

There are five key models of port management, classified in accordance to the ownership by the public or private sectors. As depicted in Fig. 2, the two extreme strategies involve full privatization or total control by the public sector.

1. **Public service ports:** Typically the federal or state government owns these ports, and appoint port officials in key management positions. The port authority owns, controls, and operates equipment, and offers a wide array of services. Port hires the labor in charge of cargo operations. Cargo handling is a service typically offered by service ports, yet performed by independent companies, which are managed by the port authorities. This arrangement has been prevailing in developing and rapidly developing economies.

Figure 3 The port management diamond model. Attaining supply & demand equilibrium. *Source: By Prof. Maria Burns.*

Many developing economies transform their ports from a service port model into a landlord model. The public sector undertakes cargo handling operations, pilotage, storage, and other services.

The case of China

The case of China, one of the global economic leaders, has two interesting practices worth sharing: While in most developed countries ports are no longer controlled by the central government, China's central government takes particular interest in its ports, recognizing their role in the nation's prosperity. China's Five-Year Plans, that is, 5-year development strategies, often name the ports and regions to materialize specific national goals. The Chinese government has divided its port authorities into five coastal regions, which correspond to nine supply chain networks, in accordance to nine main cargo types. The Chinese government works closely with these ports' municipalities, to set goals, allocate resources, decide on Free Trade Zones and industrial zones, shipbuilding activities, trade routes, and inland interconnectivity.

Therefore, the fact that Chinese ports of Shanghai, Shenzhen, Qingdao, Tianjin, and others are ranked among the world's top ports, is neither a lucky break, nor a coincidence.

This impressive national strategy makes Chinese ports unique.

2. **Tool ports:** Typically, the port authority owns, develops, and manages the port's land, infrastructure, and most assets. The private sector -appointed or approved by the port authority- undertakes the cargo handling operations, whereas the port authorities still own the equipment. This model is an attractive choice for port authorities seeking to benefit from public-private partnerships (PPP), as they can use initial capital investment to expand their market share, while retaining up the public sector ownership. This simple and fast model is ideal for ambitious port expansion plans, and is typically adopted by smaller and medium ports, or developing regions.

Many ports are shifting from this model toward a service model, for example, by allowing shipping companies and contractors to be more involved in the cargo handling operations and other services.

As seen in Fig. 3, The Tool Ports model is a hybrid between service and landlord ports, whereas the semi-privatized ports are hybrids between tool ports and Fully Privatized ports. There is a need to make a distinction between service and tool ports, as over the past years these types have been overlapping, especially in terms of financing and public control.

3. **Landlord ports:** These are characterized by a public-private coalition, where the port authority provides the legal and administrative foundation, while private companies invest in cargo handling equipment, and other facilities (Burns, 2018a). Private companies have the option to lease land, terminals, storage areas, on a short or longer-term basis. Thus, concession agreements may have a duration of several decades, with many energy, chemical and other company types leasing for 50 or 100 years (Burns, 2018b). This model is very common for mega-ports and ambitious middle-sized ports. It is worth observing that the long-term concession agreements provide the port with financial and commercial stability, whereas the partnering companies contribute to the regional economic growth, through clustering activities. These companies act as money magnets, as their dynamic supply chains consisting of thousands of suppliers and buyers, divert a part of their business near the hub port. The ports of New York/New Jersey, Houston, and Antwerp, among others, fall into this category.
4. **Corporatized ports:** This is a popular choice for nations not wishing to fully privatize their ports. A hybrid between a landlord and a privatized port model, the corporatized option allows a government-owned, autonomous arrangement, while the private sector manages terminal operations. The public sector remains a major stakeholder, while the shareholders make administrative

and strategic decisions. Although airports have successfully implemented this model, the maritime industry has not advanced as much. Most nations implement public administration protocols to manage their ports. On one hand, the private sector provides insight to strategic decisions, as they are industry-savvy and adaptable enough to meet the short-term and longer-term market needs. In addition, the affluent private sector can always provide financial support to seaports, by enabling access to capital markets, have the commercial liberty to regulate prices. Investments will be driven by market demand. In addition, operating costs can be reduced through the elimination of bureaucracy, a better understanding of the typical market performance (input/output). Port authorities that have adopted this model include ports in the Netherlands, Australia, etc.

5. **Fully privatized or private service ports:** This model reflects the ultimate port privatization, with the port's ownership and policies being fully transferred from the public to the private sector. Agreements stipulate which, if any, functions are still retained by the public sector. Ports in the United Kingdom, Australia, and New Zealand, have selected this ownership style. Despite the commercial benefits of this option, it may not adequately protect a nation's borders in case of war, and may impose increasing security risks. Contractual agreements between the port's government and the private owners, should stipulate both parties' duties in case of a future security threat, while defining each parties' role in issues of national security.

Port managers and maritime professionals must keep in mind certain strategic considerations:

- A port's ownership style is closely related to its nation's political regime, its geopolitical role (e.g., warfare, tensions with neighboring countries), and its economic development level. For example, the Chinese central government controls all national ports and terminals in a Public Service arrangement. On the other hand, privatization has been adopted by countries like England, Australia, and New Zealand, among others. These nations' geographical location, combined with lack of territorial disputes at the time of privatization, encouraged their governments to privatize.
- The golden means here entails the Landlord ports style: this is the most common style, and is preferred by many advanced and emerging economies as it combines the best of both worlds.
- The global market conditions, and stakeholders' pressures or preferences, may instigate the change from one ownership style to another.
- While some decisions are irrevocable (e.g., once a port is privatized, it is not likely to be returned to the public sector), it is common for port authorities to change ownership type, that is, shift from a tool port to a landlord port.
- Modern ports combine private and public functions. They adopt economic multiplier strategies to maximize efficiency. Successful performance derives from increase of trade volume, productivity in cargo handling, and other services. Often the role of public and private sectors is not well defined in the contractual stipulations, thus generating strategic and operational complications.

Port Efficiency as a Central Theme of Port Management

The 21st century is an era of unprecedented changes in the global landscape, introducing geopolitical, technological, regulatory, banking, and operational changes. These radical changes have dictated the need of revisiting the role of port management. Globalization has increased port competition, forcing managers to intensify their business development strategies. Their goal is to allure their stakeholders, be it financial institutions, shippers, supply chain partners, or the community.

As depicted in Fig. 3, port strategy seeks to attain supply and demand equilibrium, by evaluating the demand, and adopting a customer-based supply strategy.

The Key Drivers for Successful Port Development Decisions

To make the best possible strategic decisions, an optimum port strategy should focus on the following drivers:

1. **Market needs:** To satisfy the global market and location-based market needs, ports need to fine-tune the ownership, management, and operating styles. Changes in the port's structure may involve public/private ownership, management, and operating arrangements;
 - a. **Key players**, namely the new versus existing key players, including both potential partners and competitors;
 - b. **Geographical trends**, that is, the think global and act global notion is required, that is, the examination of regional versus global supply chain trends and development;
2. **Growth and industrial clusters:** Clusters of economic growth and industrial activities are created in port-cities as a result of:
 - a. Policies aiming at regional development.
 - b. When several companies, part of the same industry or supply chain, decide to locate in a particular port-city, to reap specific benefits (e.g., specialization, technology, infrastructure, vicinity to exporters, producers, buyers, etc).

The presence of a cluster in a port is extremely beneficial, for all entities involved. It ensures sustainable development, and mutual growth through parallel activities. It enhances the port's growth, and prolongs global prominence. What many mega-ports have in common is the presence of industrial, financial, or other production clusters.

As specific industry clusters are created in the region, or within the port's global supply chain, the ports' stakeholders have specific requirements, for example, new equipment, terminal expansion, increased security, etc. In addition to procedural and operational improvements, stakeholders' requirements may involve asset management and new investments.

3. **Market cycles:** Business cycles reflect the supply-demand equilibrium at any given stage of the economy. There is a need to adopt strategic decisions to market cycles, accurate forecasting, and being proactive in view of market fluctuations. Market cycles are supply-demand driven fluctuations, driven by a myriad of factors, including geopolitical tensions, trade agreements, new regulations or technologies, and others. While ports cannot always leverage market demand, or change the trends of market cycles, they can always adopt the supply side of the equation by sustaining efficiency through optimizing capacity. This includes decisions on the optimum size, configuration, and decisions on land acquisition, number of terminals, and types of ships to be hosted. An efficient and well-organized port enjoys an optimum balance between automation and labor.

4. **Administrative structure: Ownership, management, and operating style:** Administrative decisions include land acquisition, port and terminal configuration, investment, maintenance and operations of the port's infrastructure, superstructures, and substructures, as well as activities involving terminals, cargo handling equipment, storage, supplying of bunkers, maintenance and repairs, and various other services.

As discussed in the port ownership section, high-level strategic decisions will seek to strengthen the port's global role, at a commercial, economic, and geopolitical level.

Interconnectivity and holistic infrastructure: decisions is another administrative responsibility. Balancing port development with the regional infrastructures, ensuring the port's interconnectivity. Port development and investment can only be commercially successful in the presence of efficient supply chain networks.

5. **Port development: Asset management and investment strategies:** Port development is an ongoing commitment evolving around asset management and port investment strategies. An efficient and effective port serves as an enhancer of the regional or national economy. Once a single entity, that is, a port commits to a significant investment, it attracts other investments that overlap or align with the cargo handling operations, supply chain, transport, etc. Port development plans are always an attractive marketing tool, which give a strong message to our global markets as to the port's successful past performance, leading to an ongoing growth. Thorough investment decisions are required, as port development involves high-risk investments, often leading to a questionable return-on-investment.

Risks of investment: The three risks port managers should consider are:

- a. **Overinvestment**, that is, being overambitious about the regional market's potential to utilize the port's new development facilities;
 - b. **Underinvestment**, that is, inadequately expanding port development plans, and missing potential opportunities for growth and commercial success, and
 - c. **Mis-investment**, that is, investing in the wrong industry segment, wrong technology, etc.
6. **Port capacity and throughput:** Ports facilitate the movement of people and cargoes from the sea to inland transportation up to the cargoes' final destination. Port throughput is typically measured by combining the number of vessel calls and cargo volumes handled within a specific time, that is, on a monthly or annual basis. Namely, port capacity is measured in terms of:
 - a. Port size, measured in acres, number of terminals, number of berths per terminal, draft, etc.;
 - b. Number of vessel calls and fleet tonnage handled per year; container ships are measured by TEUs (20-foot-equivalent unit);
 - c. Annual cargo volume handled, measured in metric tons for most commodity types, and TEUs for containerized cargoes;
 7. **Automation and technology, versus labor decisions:** Automation is the new buzz word, asking port managers to consider the soft spot between becoming fully automated (at the expense of thousands of displaced workers), or retaining their core manpower. This is one of the toughest decisions modern port managers need to make, as this is a transition stage in automation, where some technologies may not always deliver as promised, whereas port employees may be inadequately prepared to embed high-tech solutions into their existing working protocols. Personnel training is also a key impact factor.
 8. **Technologies: new cyber platforms: ACE, Blockchain technology, etc.:** Without a doubt, blockchain platforms, single window Automated Commercial Environment (ACE), and paperless trade is the new norm for modern ports. Cyber space capabilities now bring a new dimension in conducting global business (Burns, 2019a).
 9. **Regulatory compliance, and embracing the new HSQE regulatory framework**, that is, regarding Health, Safety, Security, Quality, and the Environment. The maritime industry is highly regulated, and the decades from the 2020s through the 2050s are becoming increasingly regulated, especially in terms of Environmental integrity. Modern ports must embrace these changes.
 10. **IMO2020, IMO2050, greener fuels, and the new bunkering era:** Modern ports must invest in low Sulfur fuel, in compliance with the IMO2020 regulations. LNG fuels, and the new generation of fuels are the new "business as usual," and modern ports need to proactively invest in collaboration with energy majors and shipowners (Reuters, 2019; Burns, 2019b).

Conclusions

This is an exciting era for maritime transportation professionals. Modern port managers need to rapidly adapt into this new global environment. Innovative technological advancements, and the creation of new supply chains, are shaping a new global setting for decades to come.

To retain their market share and global/regional prominence, modern ports have to keep abreast of market developments, technologies, and implement efficiency strategies. Port efficiency and expansion do not only involve high levels of investment, but also entail high risk, in a global setting where “business as usual” is no longer the norm. We must adopt to the new era of groundbreaking changes, involving both tremendous opportunities and unique challenges.

Introduction

Seaports are key nodes in global logistics networks and consequently contribute to the efficiencies of the associated global supply chains. Changes in supply chains have forced ports and terminals to seek effective integration in these supply chains when delivering value to shippers and third-party logistics service providers (Robinson, 2002). Ports are thus part of complex systems operating in an uncertain logistics environment. They are also places where a number of port stakeholders provide products and services and create value together. The interests of different port stakeholders, that is, port authorities, port users, service providers and related communities, in economic, social, and environmental issues, are sometimes in conflict (Notteboom and Winkelmans, 2003). Port managers increasingly rely on stakeholder relation management practices to secure long-term relations with key stakeholders (Dooms and Verbeke, 2007). To this end, port performance measurement (PPM) has become an important tool in stakeholder relation management and to achieve a sustainable competitive position.

Over the past three decades, PPM has become a well-established segment in port-related academic literature (see Pallis et al., 2011; Woo et al., 2012) but there are still research gaps to be filled within the context of the emerging development of port logistics. First of all, the existing literature tends to focus on limited dimensions of PPM or specific areas of ports. Such a fragmented approach may fail to take into account new issues and challenges faced by ports. The extant port literature mainly introduces lists of PPIs to measure the productive and allocative efficiency of port/terminal operations (i.e., operational efficiency), focusing more on terminal quayside operations via the application of data envelopment analysis (DEA) and stochastic frontier models (Cullinane et al., 2002; Tongzon, 1995). Compared to port efficiency studies, existing studies focusing on port effectiveness (i.e., Brooks and Schellinck, 2013) are mostly restricted to the dimension of customer satisfaction using qualitative PPIs (i.e., service effectiveness). In this regard, PPM should consider the different natures of PPIs. Using only quantitative PPIs is not sufficient to measure and diagnose performance (Beamon, 1999).

Secondly, there is little literature available on the development of a systematic approach to address the multi-stakeholder dimension in PPM. PPM demands a stakeholder-driven approach to cover the wide-ranging objectives and desired results of stakeholders. This can be achieved by integrating a multi-stakeholder dimension in a PPM framework which takes into account the corresponding port performance indicators (PPIs). These stakeholder-specific PPIs need to be aligned with organizational goals and strategies (Kaplan and Norton, 2004; Neely et al. 1995) and present a clear picture of the organizational performance (Gunasekaran et al., 2001). Moreover, the range of port activities that port stakeholders are concerned with, requires a focus on a multi-dimensional set of quantitative and qualitative PPIs. Using only one dimension (e.g., financial measures) in a performance measurement setting is no longer sufficient to cover all related issues for the new business environment (Miller and Vollmann, 1985). The importance of non-financial (i.e., intangible assets) measures is enhanced and the integral application of multi-dimensional measures (i.e., both financial and non-financial) for performance measurement have been continuously acclaimed (Neely et al., 1995).

In order to fill these research gaps, we present a hybrid approach of a fuzzy logic based evidential reasoning (FER) method (Yang and Xu, 2002), a decision-making trial and evaluation laboratory (DEMATEL) tool (Gabus and Fontela, 1973) and an analytic network process (ANP) technique (Saaty, 1996) to measure four major container ports in South Korea. It answers the related questions of "what to measure" and "how to measure" port performance. Such a PPM method is needed not just to meet the needs of port stakeholders, but also to enrich the diagnostic tools available to support decision-making in complex port/terminal systems operating in an uncertain environment. In the next section, the proposed port performance measurement (PPM) method and

Figure 1 Port performance measurement (PPM) framework. Source: Ha et al. (2017)

theoretical justification to select PPIs are described in detail. In Section 3, an overview of the hybrid approach is applied to a case study of Korean container ports for practical insights. Finally, the chapter concludes with a discussion of the results the industrial and academic implications and recommendations for further research.

A Conceptual Discussion on the Port Performance Measurement (PPM) Method

Port Performance Measurement Process and Methodology

The objective of the proposed PPM framework is to identify most crucially needed PPIs for each group of port stakeholders and to develop a powerful performance measurement tool. In the framework, various disciplines such as uncertainty and interdependency among the PPIs are considered to deliver more practical applications in PPM. As seen in Fig. 1, the needs of different stakeholders were investigated in the first phase and their associated PPIs were derived in the second phase. To this end, we identified crucial interests in major (container) ports investigating stakeholders' goals and objectives, and discussed them with 10 port stakeholders.¹ Conflicts of interests between stakeholders require them to interpret others' assertiveness rightly. Consequently, the analysis of their interests and needs on various dimensions of port activities becomes essential. The six dimensions defined in this chapter cover the range of port activities to cope with new evolutionary changes, to measure and communicate their impacts on society, economy and environment and to be consistent with their goals. Then, through a literature review and an analysis of industrial practices the associated PPIs were identified and then confirmed by the panel of ten experts to assess the suitability of the potential indicators and to test the feasibility of the selected indicators (Bagozzi et al., 1991). The majority of the experts commented on all dimensions for content validation. Previous studies on port performance generally consider the PPIs as independent attributes. However, considering PPIs as independent and irrelevant to each other is not realistic any more to solve multiple criteria decision making (MCDM) problems in complex port activities and operations (Lee et al., 2013). In order to address this issue, we use DEMATEL to quantitatively identify whether there are interdependent relationships among the PPIs, while ANP is applied to determine the intensity of the relationships among the PPIs. Furthermore, FER is applied for dealing with uncertainties presented in the evaluations of the selected PPIs. In summary, the proposed method for a hybrid PPM system consists of four steps²:

1. Investigate the performance needs and interests of different stakeholders and translate them into corresponding PPIs for each group of stakeholders.
2. Find proper methodologies to deal with various features of the PPIs (i.e., interdependency, uncertainty and MCDM).
3. Assign PPIs' interdependent weight (using DEMATEL and ANP) and evaluate PPIs' performance (degrees of belief (DoB)) with respect to each alternative.
4. Synthesize the evaluations of PPIs with their weights using fuzzy rule-based ER algorithm and utility technique (IDS software).

¹The group included six industrial experts who have been working in shipping and port industry for more than 15 years with PhD (one expert from a shipping line), MSc (three experts from terminal operators, a shipping line and a forwarder), and BA (one from a terminal operator and a forwarder, respectively) degrees participated in the judgements. Two professors who have more than 15 years teaching and research experience as well as they are (ex)member of port committee participated in the survey. Lastly, two experts from government/port authority (one department manager and one managing director) who have been working for port logistics departments participated in the survey.

²The detailed description of the employed methods is discussed in Ha and Yang (2018).

The Conceptual Development of the Port Performance Indicators (PPIs)

Seaports are integrated process platforms where a number of port stakeholders interact in port activities related to cargos, vessels and other transport modes. Ports need an alignment of seaside, intermodal/multimodal, and landside logistics to achieve an efficient movement of the physical (i.e., cargos) and non-physical (i.e., information) flows (UNCTAD, 2004). To this end, PPIs in a PPM framework need to reflect these performance aspects. Moreover, PPIs evaluations need to be conducted with inputs from associated stakeholders. This may assist decision makers not only in diagnosing both the efficiency and effectiveness aspects of performance but also in identifying the strengths and weaknesses of ports. Based on this, six dimensions with their associated 16 principal-PPIs and 60 PPIs are defined as particularly relevant factors for port stakeholders. These dimensions include core activities (CA), supporting activities (SA), financial strength (FS), users' satisfaction (US), terminal supply chain integration (TSCI), and sustainable growth (SG) (Table 1). It is noteworthy that the discussions on each dimension are aimed at identifying PPIs for container terminals, focusing on their internal and external activities, but the PPIs are assessed by associated port stakeholders. Thus, the term container port performance refers to the performance of a collection of container terminals in port area.

The core activities (CA) relate to the core function of seaports, for example, vessel operation, cargo operation and other activities regarding container transfer or transit from ports to vessels and other transport modes (or vice versa) in container terminal area. The

Table 1 The hierarchy of port performance indicators (PPIs)

<i>Dimensions</i>	<i>Principal-PPIs</i>	<i>PPIs</i>	<i>Literature</i>	<i>Note^a</i>
Core activities (CA)	Output (OPC)	Throughput growth, vessel call size growth	UNCTAD, 1976; De Monie, 1987; Tongzon 1995; Cullinane et al., 2002; Brooks, 2006; Woo et al., 2011	QT; data input from TO, PA and GOV database
	Productivity (PDC)	Ship load rate, berth utilization, berth occupancy, crane productivity, yard utilization, labor productivity		
	Lead time (LTC)	Vessel turnaround, truck turnaround, container dwell time		
Supporting activities (SA)	Human capital (HCS)	Knowledge and skills, capabilities, training and education, commitment and loyalty	Marlow and Paixão Casaca, 2003; Kaplan and Norton 2004; Albadvi et al., 2007; Brown et al., 2011; Woo et al., 2013	QL; data input by TO
	Organization capital (OCS)	Culture, leadership, alignment, teamwork		
	Information capital (ICS)	IT systems, database, networks		
Financial strength (FS)	Profitability (PFF)	Revenue growth, operating profit margin, net profit margin	Su et al., 2003; Bitchou and Gray, 2004; Brooks, 2006	QT; data input from TO and GOV database
	Liquidity & solvency (LSF)	Current ratio, debt to total asset, debt to equity		
Users' satisfaction (US)	Service fulfilment (SFU)	Overall service reliability, responsiveness to special requests, accuracy of documents & information, incidence of cargo damage, incidence of service delay	Marlow and Paixão Casaca, 2003; Woo et al., 2011; Brooks and Schellinck, 2013	QL, data input by SL, FF and 3PL QL, data input by TO, SL, FF and 3PL
	Service costs (SCU)	Overall service cost, cargo handling charges, cost of terminal ancillary services		
Terminal supply chain integration (TSCI)	Intermodal transport systems (ITST)	Sea-side connectivity, land-side connectivity, reliability for multimodal operations, efficiency of multimodal operations	Bichou and Gray, 2004; Notteboom and Rodrigue, 2005; Panayides and Song, 2009; ESPO, 2010; Woo et al., 2013	
	Value-added services (VAST)	Facilities to add value to cargoes, service adaptation to customers, capacity to handle different types of cargo, tailored services to customers		
	Information/communication integration (ICIT)	Integrated EDI for communication, integrated IT to share data, collaborate with channel members for channel optimization, latest port IT systems		
Sustainable growth (SG)	Safety and security (SSS)	Identifying restricted areas and access control, formal safety and security training practices, adequate monitoring and threat awareness, safety and security officers and facilities	De Lagen, 2002; IMO, 2002; Peris-Mora et al., 2005; Darbra et al., 2009; ESPO 2010; Woo et al., 2011	QL, data input by TO, PA and GOV
	Environment (EVS)	Carbon footprint, water consumption, energy consumption, waste recycling, environment management programs		
	Social engagement (SES)	Employment, regional GDP, disclose of information		By PA and GOV

^aNote: FF, freight forwarder; GOV, government; PA, port authority; QL, qualitative PPI; QT, quantitative PPI; SL, shipping liner; TO, terminal operator.

Source: Ha et al. (2017)

CA have traditionally, and most frequently, been assessed by scholars and industry practitioners (Cullinane et al., 2002; Tongzon, 1995; UNCTAD, 1976) using different types of taxonomies, such as output, productivity, capacity utilization, and efficiency. Productivity is one of the most important criteria guiding port choice by shipping lines (Murphy et al., 1992). The term productivity refers to how efficiently resources (i.e., labor, equipment and land) are being used. The outputs generally considered include production, throughput and profit (Bichou, 2006). Output thus refers to the total quantity of work performed in a port over a period of time without considering the resources utilized (De Monie, 1987). The lead-time refers to the speed at which activities are performed. This term gained in importance by the introduction of just-in-time (JIT) production (De Treville et al., 2004), where it is defined as the time that elapses between the start of a process and its completion. Schmenner (2004) stressed that companies achieving a higher competitiveness through a combination of speed and variability reduction and productivity improvement would have a higher performance than when focusing on only one aspect.

Supporting activities (SA) refer to the maintenance of internal resources to improve an organization's effectiveness and/or efficiency. Kaplan and Norton (2004) stressed that desired strategic outcomes could be achieved by appropriate deployment and effective utilization of intangible assets in the information era. A value-oriented organization based on collaboration, trust, sharing, learning, and openness tends to achieve desirable outcomes such as efficiency, effectiveness, and innovation (Alavi et al., 2006). There is a need of reliable human resources (HRs) that cannot be easily imitated by competitors (Marlow and Paixão Casaca, 2003). Employees who have the right skills, talent and knowledge contribute to enhancing the organization's internal processes and performance (Kaplan and Norton, 2004). A higher worker commitment and loyalty leads to a higher workplace performance (Brown et al., 2011). Albadvi et al. (2007) found a statistically significant correlation between ICT and firm performance.

The financial strength (FS) dimension concerns financial profitability and stability. Profitability measures a firm's ability to generate profit relative to land, labor and capital inputs. Liquidity is to measure the firm's ability to pay its short liability whilst solvency covers its long-term liabilities. Irrespective of the type of industries, financial performance is very important for managers and investors. This is reflected by the many PPM approaches in literature. UNCTAD (1976) introduced revenue and cost items and classified major port cost items into labor costs, equipment costs and capital costs. Marlow and Paixão Casaca (2003) suggested the measures of cost items in the lean port process. Su et al. (2003) used profitability, solvency and return on investment as financial indicators for the balanced scorecard (BSC) based comprehensive performance measurement systems. Brooks (2006) identified specific revenue and cost items that are widely used by port operators in 42 ports located in ten different countries.

The aforementioned PPIs can be measured based on the information gained internally from terminal operators. Therefore, we take into account externally generated information to represent port users' stance for performance measurement. Previous literature mainly investigated whether a service quality delivered by ports meets port users' needs in terms of timing, quantity and quality (Brooks and Schellinck, 2013). In addition, we suggest to include an indicator to measure port agility, or the speed with which the port service provider responds to customers' special requests (Marlow and Paixão Casaca, 2003). These are underpinned by the growing number of studies using the SERVQUAL on service quality in the port industry (Pantouvakis et al., 2008). Woo et al. (2011) used various port service prices as a service quality measure. Service cost is considered as one of the most important criteria which affects port selection by port users and determines port competitiveness when service quality is ascertained (Yeo et al., 2014). Consequently, low port service charges are a key driver to attract customers (Woo et al., 2011).

Ports have a key role to play in supply chains. In this context, higher integration and coordination between the players in supply chains lead to a higher competitiveness (Panayides and Song, 2009). Seaport terminals should provide a reliable and adequate multimodal process such as sea/land side connectivity, multimodal transport integration in order to attract trade flows and increase a port's competitiveness (Woo et al., 2013). In addition, they should provide value-added services to better meet the objectives of the supply chain system (Panayides and Song, 2009). Furthermore, information & communication systems (ICS) integration cannot be excluded for TSCI; it measures the establishment and use of seamless communication systems and the degree of collaboration with other partners (Bichou and Gray, 2004; Notteboom and Rodrigue, 2005). Marlow and Paixão Casaca (2003) demonstrated that integrated IT systems would contribute to total cost reduction in supply chains.

Sustainability refers to the intersection of social, environmental and economic contributions that deliver long-term effectiveness for the natural environment, society and firms (Carter and Rogers, 2008). Despite the wide adoption of the term sustainability, the application of the concept to the maritime industry is of recent date (Lam, 2015). Due to legislations and the requirement to fulfil corporate social responsibility (CSR), ports are urged to reduce environmental impacts and to enhance safety, security and social and economic responsibility (ESPO, 2010). Hence, ports need to pay more attention to the promotion of long-term sustainable growth with ecological health and social and economic contributions. In the long term, port efficiency and competitiveness can be gained from the appropriate safety and security scheme (Woo et al., 2011) and monitoring and implementing environmental management systems (EMS) in maintaining port operations (Darbra et al., 2009; Peris-Mora et al., 2005). Furthermore, the contribution of ports to society and the economy is important in the context of CSR (De Langen, 2002; Grewal and Darlow, 2007).

Based on the insights presented earlier, there is a need for a high degree of excellence of modern ports in a multi-stakeholder perspective which can deliver internal and external satisfaction. The six dimensions for PPM are intertwined in practice. With regard to "employment" in SG, for example, an alternative port can be judged with a good performance on the "employment" PPI when the port has a huge contribution to create an employment opportunity or maximizes employment to fulfil SCR. However, the situation could simultaneously deteriorate the FS of the firm, leading to increased costs and can have an adverse effect on "labor productivity (throughput/number of employee)" in CA. In this regard, the mixed use of benefit and cost PPIs needs to be taken into account to represent interests of different port stakeholders in the context of port performance measurement.

Note: ¹The input data for the weight evaluations was obtained by the panel of expert group while ²the evaluations of PPIs' performance with respect to each container terminal were conducted using inputs gained from different stakeholders (i.e. questionnaire survey for qualitative PPIs; secondary data for quantitative PPIs)

Figure 2 A hybrid methodology for port performance measurement. Note: ¹The input data for the weight evaluations was obtained by the panel of expert group while ²the evaluations of PPIs' performance with respect to each container terminal were conducted using inputs gained from different stakeholders (i.e., questionnaire survey for qualitative PPIs; secondary data for quantitative PPIs). The Use of the Hybrid Methodology for Port Performance Measurement in South Korea

Based on the methodology (Fig. 1) in section "Port Performance Measurement Process and Methodology," this section uses an analysis of four major container ports in South Korea to demonstrate the detailed quantitative modelling for PPM using a hybrid approach of DEMATEL and ANP incorporating FER and utility technique, which is shown in Fig. 2. The case analysis is conducted to identify and prioritize their PPIs from multiple stakeholder perspectives. In order to remain competitive, these ports need to meet the requirements of (global) shippers, shipping lines and third-party logistics service providers while withstanding the competitive forces exerted by rival ports in the region. The methodology could equally be applied to other performance-driven port regions around the world. As seen in Table 1, the PPIs include various types of numeric and subjective data to reflect the complexity of port/terminal business environments. The data collection for the evaluation of all PPIs' performance, see Ha et al. (2017).

The Use of DEMATEL and ANP to Analyze PPIs' Interdependent Weights

An integrated method of DEMATEL and ANP has been proven to be a successful tool for measuring dependence and feedback among elements in complex decision problems in various applications (Buyukozkan and Cifci, 2012). In this section, the local weights of 60 PPIs obtained by AHP are shown in Table 2. Further computation has been conducted to obtain global weights of the bottom level PPIs by multiplying their local weights with the ones of their associated upper level criteria. For instance, the global weight of "throughput growth (OPC1)" can be obtained as 0.083 (=0.12 (the global of output (OPC)) × 0.696 (the local weight of throughput (OPC1))). The global weights of 60 PPIs at the bottom level are demonstrated in Fig. 3. The results derived from ANP suggest that throughput growth (OPC 1) is the most important PPI, which has a relative importance value of 0.083, followed by vessel turnaround (LTC 1, 0.071), crane productivity (PDC 4, 0.048), overall service reliability (SFU 1, 0.037), vessel call size growth (OPC 2, 0.036), and IT systems (ICS 1, 0.036). In contrast, waste recycling (EVS 2, 0.002), water consumption (EVS 4, 0.002), and carbon footprint (EVS 1, 0.002) under environment (EVS) are the least important PPIs. The top 10 rank PPIs in the ANP results include four PPIs under core activities (CA), three PPIs under supporting activities (SA), two PPIs under financial strength and one PPI under users' satisfaction (US). The global weights obtained are used as inputs for FER method.

Port Performance Measurement in South Korea Using FER

The synthesis of four ports against all PPIs together with their weights in this chapter was conducted by IDS software incorporating the ER algorithm and utility technique. The results derived from IDS are shown in Tables 3–5 and Fig. 4 with respect to different ranking criteria. The performance of individual PPIs with respect to the alternative ports is shown in Table 3. They provide direct information on analyzing performance of each port activity driven by each stakeholder, which makes port managers possible to interpret the performance results straightforwardly. For example, both the container throughput growth and vessel

call size growth PPIs in Busan North Port are shown as a negative growth. However, the ship load rate, a ratio of the combined two PPIs of container throughput volume (TEU) and an average vessel call size (GT), is performing well with a performance score of 0.8471. Even though the number of vessel calls to Busan North Port saw a relatively small decrease from 7702 in 2012 to 7386 in 2013 (−4.1%), the total gross tonnage (GT) of the vessels decreased radically from 136,448k GT to 113,405k GT (−16.9%). This indicates that smaller sized vessels came into Busan North Port in 2013 compared to the vessel size in 2012. Accordingly, container throughput decreased dramatically (−12.5%) but the decline was not as dramatic as the drop in vessel capacity calling the port (−16.9%). This leads to the remarkable performance result of the ship load rate in 2013 (81.69 TEU/GT). Moreover, the higher number of small sized vessel calls leads to a higher berth occupancy rate (the ratio of time that a vessel is occupying a berth, 1.0000) because the vessel berthing practices in general are conducted in terms of berth (identity) number regardless of berth capacity, but relatively lower the berth utilization performance (TEU/berth length, 0.704). Busan North Port performs moderately in other PPIs but shows a very poor performance on all profit PPIs. This is an expected result due to the poorest performance on the container throughput PPI that generates revenues for terminal operators. It might be noted from the result that terminal operators in Busan North Port are required to make an effort to create the coopetition strategy recommended by Song (2002) to face intensified port competition.

Beyond the individual PPI's performance, port managers can analyze performance at a higher level of abstraction (i.e., 16 principal PPIs and six dimensions). Fig. 4 demonstrates the performance scores of the 16 principal-PPIs, which is derived from the transformed values through the mapping process from the lowest level PPIs to their associated principal-PPIs, and the lowest level PPIs' weights. The results can lead to performance scores for the six dimensions (Table 4) and the overall performance results of each alternative port (Table 5). From the case study results the following conclusions can be drawn. The results suggest that Busan New Port shows the best results, followed by Incheon Port (Table 5). The difference is significant especially between the adjacent ports of Busan New Port and Busan North Port. Busan North Port is assessed to be the least competitive port with the lowest performance especially in terms of output and profitability (see Fig. 4). Busan New Port outperforms the other ports in terms of output, lead-time, profitability, intermodal transport systems, value-added services, information and communication integration, safety and security, environment and social engagement but is less competitive at the level of two principal-PPIs such as liquidity & solvency and service costs. This is because the five terminal operators in Busan New Port started up operations from 2005 to 2011 respectively. So there has been a rather recent heavy initial capital spending for port superstructure, state-of-the-art systems and equipment. The required capital is generally raised from financial institutions and investors through project finances. With regard to the service costs, the adjacent port, Busan North Port, lowered its service price to secure its market share from the moment Busan New Port started operations (based on interviews with terminal operators in Busan Port). The "lower price" strategy is the more preferential strategy when port operators adjust themselves in a changing business environment characterized by intense port competition. On the other hand, Incheon Port has its strengths in terms of human capital, organization capital, information capital and liquidity & solvency, accordingly in supporting activities and financial strength. Another striking feature of ports demonstrates that a very similar trend but a clear difference in performance score and ranking. For example, they show relatively poor performance results on output, productivity, environment, social engagement and profitability while they outperform in terms of lead-time and safety and security

(see Fig. 4). These results can provide a validation of the proposed methodology as the case ports are in pursuing similar objectives³ under a similar logistics environment (i.e., similar organizational structure, port governance, policy and economic condition, etc.). At the same time, they are also a weakness of this chapter as the results are only drawn from Korean port cases which indicates further empirical study in different regions/areas needs to be conducted. From the case study results it is possible to provide the strengths and weaknesses of the four ports. Accordingly, decision makers in the ports can identify the particular areas for improvement to enhance their competitiveness. These results provide an important contribution for decision makers to enhance their port performance based on any necessary comparisons. Furthermore, it can be used for a longitudinal study to investigate the improvement of ports within different timeframes.

Discussion and Conclusion

This chapter presented a PPM study with two new features, one is to take into account PPIs' interdependency while the other is to measure the interdependent PPIs in a quantitative manner by taking the perspectives from different port stakeholders. The result represents an effective performance measurement tool in complex port/terminal systems, which is validated through the case study of four major container ports in South Korea. This offers diagnostic instruments to decision makers in identifying the particular areas for improvement. In order to strengthen the research validation and its contribution to industry and academic research, we adopt the feedback from four senior managers in terminal operating companies located in each port. The development of the measurement instruments and the hybrid quantitative model to measure port performance is perceived as a major contribution. On the basis of the multiple objectives of key stakeholders, the PPIs crucially needed for measuring port performance were identified. They include both quantitative and qualitative items to offer diagnostic instruments to port managers, aiming to meet the different needs of port stakeholders. The identified PPIs within multidimensional conceptualizations characterize that (1) they are very specific measures to represent direct information on port activities; (2) they are very balanced measures to represent both internal/external aspects and efficiency/effectiveness aspects. According to the feedback from the senior managers, a set of quantitative PPIs have generally been utilized because the data can be readily available, or because the qualitative PPIs are too ambiguous to interpret them in a meaningful way. Accordingly, they cannot be used frequently together despite the need for performance measurement. The implication is that the hybrid approach can successfully deal with both quantitative and qualitative PPIs within a single framework. The results yielded by the hybrid approach provide for the ranking of the ports in terms of their overall performance with respect to multiple PPIs as well as a PPI's ranking with a single performance value. The interpretation of the results of the hybrid approach is very straightforward. This feature enables port managers to identify the strengths and weaknesses of the ports in terms of each individual PPI, principal-PPI and dimension, and offers insights into them to find the particular areas in need of special attention. Therefore, on the basis of the conclusions derived from the case study, this chapter provides port managers with valuable insights as this framework allows them (1) to recognize current strengths and weaknesses of each port; (2) to better understand the conditions and status of their competitive ports; (3) to prioritize investment to improve competitiveness and customers' satisfaction by focusing on the poor performing areas or by adjusting their strategies based on the relative importance of PPIs.

In recent years, we have witnessed tremendous technology progress in almost every aspect of our lives. Smartphones, GPS navigators, Bluetooth devices, tablets, and other wireless devices are becoming ubiquitous. Innovations in sensors, cameras, computers, wireless communications, and visualization techniques, such as virtual reality and augmented reality, now make it possible to gather, analyze, and project data forward (in near real-time and otherwise) in ways that have never before been possible earlier. At the same time, the quick evolution of technology poses interesting challenges by way of modeling (predicting) travel needs into the future as well as to understand travel behavior considerations in a fast-changing landscape. For example, autonomous vehicles (or driverless vehicles) are likely to emerge in the marketplace within the next few years, even though their adoption and use in mainstream transportation may take longer. Such vehicles can act as probes for a variety of transportation operations, and collect voluminous amounts of data that can be harnessed for effective transportation management. The key issue is how to deal with such voluminous and diverse amounts of incoming data per unit of time, and translate them into usable information for near-real time operations purposes or for long-term planning purposes. This is a challenge, given the data reliability required to translate data into actionable intelligence, especially for such safety applications as collision avoidance. In addition, predictive analytics to translate data into information requires the ability to deal with data that may be from multiple sources, highly noisy, heterogeneous, and high-dimensional with complex interdependencies. There is also a need for a data architecture to store such data and retrieve quickly. Thus, it is important that scholars are knowledgeable about the diversity of data sources, data-collection and integration approaches, data storage and retrieval, simulation and optimization techniques, mathematical, statistical, and econometric approaches, visualization techniques, and prediction methods/algorithms used in transportation analysis.

The articles in this section deal with a range of topics associated with transport data collection, data management, and transport modeling, including (1) methodology-oriented contributions (agent-based microsimulation methods, computational methods, spatial choice and general choice models, demand-supply feedback loops, use of Geographic Information Systems in data architectures and analysis, forecasting methods, multicriteria decision-making, and emerging new analytic tools), (2) topic-oriented contributions (trip departure and route choice, trip-chaining, vehicle ownership, shared mobility, recreational travel, commuting patterns, demand management and pavement demand strategies, parking demand, public transit systems, autonomous vehicle adoption/use, and ride-hailing patterns), and (3) data collection/software-related contributions (including discussions of a national travel survey database and transportation statistics/databases more generally, and a review of transport modeling/planning software). Many of the articles have cross-cutting themes with articles in other sections of the Encyclopedia, especially those dealing with Transport Planning and Policy. The collection of cross-cutting and inter-disciplinary contributions should be valuable to scholars focused on modeling and analysis, transport applications, data architecture design, and algorithm development for translating data into information in near-real time and planning, just to identify a few areas.

Computational Methods

Computational methods in transportation involve developing and using mathematical models of a certain complex phenomenon or system, for example, flow of traffic at an exit ramp or individuals using public transit system. Transportation analysts can use these models in a computer program to numerically predict the behavior of the modeled system in “what-if” scenarios as well as optimize the system for various objectives under certain constraints. Computational methods used in transportation can broadly be classified into two categories: deterministic and stochastic (Möller, 2014). Fig. 1 shows a more detailed hierarchy of various types of computation methods employed in transportation.

Deterministic Computational Methods

Given a particular set of inputs, deterministic computation methods will always produce the same set of outputs. Typically, the deterministic methods are used to simplify the complexity of the problems, for easily finding the solution, or when the scenario we are trying to model is only being observed in a very controlled environment. In reality, phenomena in transportation systems are not purely deterministic, but some are close enough and can be approximated using deterministic computational methods. For example, train schedules on dedicated tracks are often considered deterministic since operators control the flow of trains and usually the demand is more or less stable, that is, trains are encapsulated in a controlled environment. If a train leaves stop A at 6:45 a.m., under normal operating conditions, it will arrive at B at 7:00 a.m., and this will happen most of the days during a year.

Deterministic computational methods are static if the phenomena we are solving do not change over time and are dynamic if the phenomena change over time. For instance, in the static equilibrium assignment, the flows between origin and destination are considered static (Ortuzar and Willumsen, 2011). This is not very realistic as it does not reflect the fluctuations of the vehicles on the roads over the day. However, for long-term planning of transportation infrastructure, this assumption may not introduce a very large error. The dynamic equilibrium assignment, on the other hand, is more suitable for representing how flow changes during the day and should be considered in the operational aspects of transportation system (Ortuzar and Willumsen, 2011). Static models are useful when the system we are trying to model does not change considerably over the observed period of time. On the contrary, if the system changes are significant over the considered period of time, it is better to use a dynamic model. In terms of computations, generally a dynamic deterministic computational method has higher complexity when compared with the equivalent static method. The variables for solving static deterministic models can be considered constant for the entire process or they may change in each step. Steady-state variables in deterministic static models are used when the modeled process remains unchanged. This type of models can be viewed as a photograph of a phenomenon at certain instant of time.

Time series deterministic computational method involves a sequence of points equally spaced over time and is somewhere in between dynamic and static, depending on how we layout the model. Time-series methods, in static form, are a set of possible initial states of our model such that each point in the series is evaluated in the model each time. In static user equilibrium with time-series variables, we assign a flow at each point in the series. Using this set of input flows, we then find an equilibrium for each point in time. On the other hand, time series in dynamic models is the evolution of the initial state over time where every point is dependent upon

Figure 1 Computational methods used in transportation.

Figure 2 Time space diagram of two vehicles along a road segment.

the value of the previous point. In dynamic user equilibrium, we assign the vehicles arriving during certain time step to the start of the time step or randomly distribute them over the time step using certain distribution, for example, uniform or Poisson. The equilibrium is then computed over time, while accounting for the arrival sequence of the vehicles.

Spatio-temporal variables in dynamic deterministic computational methods reflect the changes of the variables (states) in space and time. Traffic flow models of a road segment are often modeled with a time-space diagram, which plots the movements of one or more vehicles in time along a given road segment. Fig. 2 shows a time-space diagram of two vehicles along a road segment, where a spatio-temporal variable is defined with a time-distance tuple (s, t) . Observe that at time t_1 , vehicle 1 has traveled s_1 meters of the road, while vehicle 2 has traveled s_2 meters, that is, vehicle 2 is closer to the end of the road segment.

Table 1 provides a list of classic deterministic computational methods commonly used in transportation.

Stochastic Computational Methods

While in reality, almost every aspect of transportation is stochastic, there are some cases that may involve higher randomness than others, for instance, the nonrecurrent congestion levels after a baseball game. Transportation analyst can model such phenomena

Table 1 Example of classical computation methods

using stochastic computational methods (Molugaram et al., 2017). Given certain state of the system, the best a transportation analyst can do is to predict the outcome by assigning a probability to it. With stochastic methods, the outcome of a state can be different even for the same set of inputs. To account for this randomness, the analyst usually evaluates the stochastic model several times for the same input and develops a mean outcome.

Let us assume a simple scenario where a person leaves home every day at 6:00 a.m. and drives to work. Here, leaving for work in a vehicle at 6:00 a.m. can be considered as the initial state. Given that the traffic on certain route is random and may vary because of weather conditions, accidents, maintenance work, number of vehicles on the route, etc., the best a transportation analyst could do is to estimate the arrival time for the person based on the initial state and approximation of the route conditions. No matter if a person leaves home every day at exactly 6:00 a.m., some days they will arrive at their office at 6:44 a.m. due to low traffic on the route, but then they could also arrive at 7:30 a.m. due to some accident on the route. Thus, the exact arrival time at the office cannot be predicted with certainty.

Stochastic computational methods can be solved by using statistical models or simulation techniques (Kutz, 2013). Statistical methods are parametric mathematical expressions, models, and techniques that extract relevant information from the raw observations in a concise form. The relevant information is usually extracted in the form of a set of parameters, for example, mode, scale, and average rate. It is assumed that the observed data are representative of the stochastic process. In the example above, let us assume that the person logs their arrival times for a whole year. By looking at the data, they observed that a probability distribution can be fitted such that the arrival time between 6:50 a.m. and 7:10 a.m. is 70%, while the probability of arriving later or earlier is 15% each. They also conclude that the mode for travel time is 1 h.

In general, the statistical model can be parametric, semiparametric, and nonparametric. In the case of a parametric model, a parametrized distribution is fitted to the observed data. For instance, the phenomenon of vehicles arriving at a signalized intersection is usually modeled by a Poisson process and by finding the headway distribution between successive vehicles. Nonparametric models are used where fitting a parametrized distribution to the data is not possible because of the high level of stochasticity. Here, methods like histogram, running average, and kernel fitting are used to estimate model. Semiparametric approaches are a combination of the previous two; part of the phenomena is modeled using parametrized distribution, while the rest is modeled using nonparametrized model.

A common parameter estimation method for statistical models is the maximum likelihood approach, where the algorithms search for a set of parameter values that maximizes the joint probability of reproducing the data using the proposed statistical model. If the search space is very complex and/or the available data size is too low, then Bayesian estimation techniques can be used to maximize the likelihood. In the case of very large amount of data, stochastic gradient descent method is used to find the optimal parameters.

Simulation methods are computer programs that abstract a real-life phenomenon using mathematical formulations and probability distributions (Ross, 1997). The idea of a simulation is to have a computer model, where transportation analysts can test different scenarios and assess their outcomes before the actual implementation, for example, studying the effects of constructing an additional lane on an existing highway. Simulation plays a useful role where the outcomes of a model are difficult to obtain with analytical expressions. Computer implementation of a simulation involves drawing from probability distributions. This is achieved by first generating a pseudo-random¹ number and then transforming it to a draw from the empirical probability distribution, which is part of the simulation. This process is known as Monte Carlo simulation. Suppose that we want to analyze the wait time at a four-

¹ Note that computers are discrete and have limiting memory, due to which generation of a true random number is not possible.

way intersection for different conditions. This phenomenon can be modeled as a queue with certain arrival time distribution for vehicles and service time distribution at the intersection for each direction. Suppose that the arrival rate is modeled as a Poisson distribution and service time as an exponential distribution. The parameter for the two distributions can be estimated from the historic data. Monte Carlo simulation can then be used to simulate the arrival time of every vehicle arriving at an intersection in each direction. Once a vehicle arrives and the intersection is empty, it will be serviced immediately and will pass through. The service time is represented by the value drawn from the exponential distribution. Service time may vary due to the initial speed of the vehicle, acceleration/deceleration, which direction the vehicle is going to, etc. In the case where there are other vehicles in the intersection, the arriving vehicle will join at the end of the queue and wait for its turn to cross the intersection. If we keep track of the time for each vehicle in the simulation, we can develop statistics like average and standard deviation of wait time. This simulation can also be used to test various what-if scenarios, for example, what will be the effect on wait time of North-bound traffic, if the East-bound and West-bound traffic increases by 30%?

There are various phenomena, where the underlying distribution is very complex and operationally it is not feasible to use Monte Carlo simulation for sampling from such distributions. Markov chain Monte Carlo (MCMC) methods are the alternative that can be used in such cases. MCMC methods use the properties of the Markov chain to indirectly sample from the underlying distribution. For instance, Gibbs sampling, a type of MCMC simulation, has been used to synthesize the population and their characteristics for use in the activity-based travel demand modeling system. It should be noted that MCMC methods involve a random walk in the search space, which could be computationally wasteful, but the properties of the Markov chain ensure that once the MCMC simulation reaches the steady state, it will be able to sample from the underlying distribution. Techniques like Hamiltonian dynamics are used to make the MCMC simulation more efficient.

Operationally, simulation methods can be classified into discrete event or discrete time simulations. In the case of discrete event simulation, the computer simulation updates its state only if an event happens. This means that the time between two consecutive state updates is not constant. For instance, in the discrete event version of intersection simulation, the state of the intersection will be updated only when a vehicle arrives. Whereas, in the case of discrete time simulation, the state will be updated every constant time interval. In the case of the intersection simulation, we will process all the vehicles arriving in an interval, for example, during 10 s, at the start of that interval. Discrete event simulation is used where the events are more randomly distributed over time and their occurrence rate is low to moderate. Discrete time event is suited for a more uniformly distributed event over time with high rate of occurrence.

Stochastic computational methods can also operate at different spatio-temporal scales, depending on the complexity of the phenomena, available computational resources, and the context of their usage. [Table 1](#) provides a list of classic stochastic computational methods commonly used in transportation.

Data Analytics

Data analytics involves examining the data observed on a complex phenomenon or system to understand, classify, characterize, and predict better. Such an analysis involves developing descriptive, diagnostic, predictive, and prescriptive models ([Chowdhury et al., 2017](#)). [Fig. 3](#) shows four main types of data analytics methods and tools available for analyzing transportation data. Both deterministic and stochastic computational methods are employed in developing these data analytics.

Descriptive Analytics

Such analytics studies the current state of a phenomenon and helps in identifying issues as well as the underlying distributions in the data. It helps as a transportation analyst in revealing the desirable and undesirable outcomes. With descriptive analytics, we can identify bottlenecks on the highways, share of the commuters using public transport, or the spatial distribution of cyclists in a city.

Transportation analyst uses classic statistical methods to analyze the historical data and provide qualitative and quantitative insights related to the transportation system. The most used techniques in transportation system analysis are tendency, distribution, and dispersion analysis. These types of analysis involve tables and graphical representations of the data that can help in the organization and understanding of the state of a system. Visualization techniques and tools like geographic information systems (GIS) are readily used in developing descriptive analytics.

Diagnostic Analytics

Diagnostic analytics aim to explain the circumstances that lead to a certain phenomenon. While descriptive analytics show the current state of the phenomenon, diagnostic analytics tries to explain *why* a certain phenomenon happens. The focus here is on finding the causation and relationship between different variables. Typical techniques used to develop such analysis include correlation analysis, pattern mining techniques like association rule mining, and multidimensional contingency table, also known as hypercubes, developed in a data warehouse.

Correlation analysis is typically applied where a small representative sample is periodically collected, for example, travel survey conducted by a municipality every 5 years. The focus here is on testing the hypothesis related to causations. Pattern mining techniques are applied on larger datasets with higher frequency, but having less information available on the actual traveler, for

Figure 3 Data analytics used in transportation.

example, bike usage data in a bike sharing system. In such cases, other datasets are overlaid, for example, land use data are overlaid on bike usage data to mine and understand the spatial usage patterns of bike sharing system. Transportation agencies may also employ large data warehouses to host information coming from heterogeneous sources, for example, smartcards, loop detectors, travel survey, traffic cameras, etc. Hypercubes are developed over these datasets to conduct diagnostic analytics.

Predictive Analytics

Predictive analytics help a transportation analyst to foresee the future state of a phenomenon given certain future conditions, for example, how will the wait time at an intersection increase with an increase in the population in the neighborhood by 15%? Given the present state and the historical data with predictive analytics, it is possible to develop a generalization, for example, parametric mathematical expression that can be used to predict future conditions. Predictive analytics mainly use hypothesis-driven approaches, data-driven approaches, or a mix of both.

In the case of hypothesis-driven approach, theoretical foundations are employed to develop a mathematical relationship for the phenomena. The form of the mathematical relationship is a priori defined. Available data are then used to prove or disprove the causal relationship defined in the mathematical relationship. For instance, the behavior of a commuter in choosing mode can be expressed as a multinomial logit (MNL) model, which has a strong foundation in consumer behavior theory and econometrics. At core, the attractiveness of a choice is expressed in form of a linearly additive parametric function and an extreme value distribution that accounts for the errors. Particular hypotheses would result in an exact form of this parametric function—it may be hypothesized that with an increase in the travel time, a mode may not be as attractive to the commuter as other modes with lower travel times. Statistical estimation methods, for example, maximum likelihood method can be used to estimate the parameters and indicators identifying their significance (e.g., *t*-statistics) in the data. The estimated significance is used to judge if certain hypothesis holds or not. Once the model estimation is finalized, it can be applied using Monte Carlo simulation to give us predictions based on the future conditions. For instance, an MNL model estimated for mode choice using the travel survey data from a municipality can be used in Monte Carlo simulation to predict the change in the share of public transit if the fare is increased by 5%. Hypothesis-driven approaches are particularly useful in the situation where predictive models need to be developed using small datasets. They also provide a well-established foundation for economic analysis, for example, investigating the willingness to pay of a population.

Data-driven machine learning approaches, on the other hand, do not assume a particular a priori form on the underlying distribution in the data and learn the distribution with an abstract structure. For instance, a deep neural network uses a structure of

hidden layers with hidden units and connections between the hidden units to learn the relationship between variables in the data. Unlike hypothesis-driven approaches, here the interpretability of the estimated model is not trivial. However, these approaches are more efficient when large amount of data is available. They are also better at capturing the higher order correlations and non-linearities in the data.

Prescriptive Analytics

Prescriptive analytics provide recommendations about how to achieve the desired outcome of a phenomenon or system. These types of analytics use the outcomes of predictive analytics to build guidelines or trace a plan for getting to the preferred outcome. Most of the time, the process may involve the use of optimization, where the objective is to find the optimal decision variables that will achieve the desired outcome. For instance, simulation-based optimization can be used to set the signal timing for intersections in a corridor. In a more complicated phenomenon, the optimization may not be operationally tractable, so a range of carefully developed scenarios are developed by the domain experts and are simulated. The outcomes from such scenarios are then compared based on different predefined criteria and the best scenario is selected. For instance, if a municipality is interested in developing a transit-oriented development, it may ask the planners and architects to recommend various scenarios based on the best practices in the design of urban built space and mix of land use. These scenarios are then simulated for the future years and their performance based on the public transit shares is evaluated.

Introduction

Historically, the main goal of transportation planning was to predict aggregate travel demand under different long-term socio-economic factors, transportation infrastructure conditions, and regional land-use configurations. These aggregate travel demand models (TDMs) were used to prioritize and build transportation infrastructure projects to meet the expected travel demand. However, constrained budgetary situation coupled with raising awareness about the importance of sustainability shifted the focus to demand management strategies that aim to change individual travel habits as opposed to building new infrastructure. As a result, disaggregate travel demand models that provide greater insights into individual travel-related decisions became increasingly popular in recent times. Activity-based models (ABMs) are a class of disaggregate TDMs that are based on the premise that aggregate travel demand is a derived outcome of the people's needs and desires to participate in activities distributed in space and time (Castiglione et al., 2015). So, the primary focus of ABMs is on understanding the factors that influence individual 'activity-patterns' including (1) the number of and type (e.g., work vs. non-work) of activities undertaken, (2) the activity locations, (3) the time and duration of each activity, (4) the travel mode used to reach the activity location, and (5) with whom the activity was undertaken. In a way, ABMs attempt to predict the complete activity diary of every traveler in the study region. Quite understandably, the development of ABMs is a data-intensive and computationally complex endeavor. Therefore, transportation planners have attempted to develop ABMs that can reasonably mimic the true behavior of travelers while maintaining practical feasibility. So, different simplifying behavioral assumptions (e.g., the sequence in which different activity-pattern decisions are made) can lead to different ABMs with different policy implications. Unlike aggregate TDMs such as the traditional trip-based four-step model that has become the standard practice for long-term travel demand forecasting, ABMs are constantly evolving to reflect new behavioral research findings and innovative transportation technologies, and to incorporate efficient computational processes.

Relative Advantages Over Trip-Based Models

Trip-based models commonly include four primary components—trip generation, trip distribution, mode choice, and traffic assignment. To some extent, these components mimic the activity frequency, destination, mode, and route choice decisions made by travelers. However, given the aggregate nature of trip-based models, they do not account for realistic constraints of space and time that dictate the choices made by individual travelers (Pinjari and Bhat, 2011). Every trip is assumed to be made independently without recognizing that all attributes (e.g., location, mode, and time) of any given trip as well as different trips made by an individual are inter-related. For instance, linked trips that begin and end at the traveler's home have fewer feasible travel mode combinations compared to three independent trips. Along similar lines, trips made by individuals belonging to the same household are also assumed to be independent in trip-based models. For instance, a full-time worker who drops-off her/his child at school during commute would continue to do so even after an additional toll is imposed because of the child-care responsibility. A trip-based model is prone to over-estimate the reduction in car mode usage under congestion pricing scenario because it does not account for such household and person-specific space-time constraints. Also, the "time" dimension is either completely ignored or treated in an ad-hoc static manner in trip-based models by assuming that a fixed percentage of trips are made during different aggregated time-periods (e.g., peak vs. off-peak). Due to these simplistic assumptions, trip-based models are prone to provide biased travel demand forecasts under demand management strategies. The disaggregate activity-based models, on the other hand, explicitly account for space-time constraints among trips made by an individual as well as trips made by other people belonging to the same household and are capable of continuous representation of time. A related advantage of ABMs is that policy impacts can be easily summarized for different population segments to support equity analysis (Castiglione et al., 2015). Also, any performance metric generated by

trip-based models (e.g., mode shares and trip-length distribution) can be produced by the activity-based models by aggregating individual travel choices.

Alternate Activity-Based Modeling Systems

Given that the focus is on the individual traveler who is the decision-making agent, activity-based modeling systems are ensembles of multiple sequential and inter-connected sub-modules that predict different activity and travel choices of individual travelers. These modeling systems are applied sequentially to all travelers in the study region to populate the activity and travel diaries of the entire population. A key step that defines the heart and soul of an ABM is the design of the behavioral framework which defines the sequence/order in which different activity-travel decisions are made by individual travelers within each household. Most ABMs have two primary steps—(1) the activity generation step in which the activity participation decisions of all individuals in each household are predicted, and (2) the activity scheduling step in which the generated activities are packaged into tours that begin and end at the home or work place of the traveler along with a host of additional predicted attributes including travel mode, destination location, time-of-day, and travel party (Pinjari and Bhat, 2011). Typically, mandatory activities such as work or school are predicted first that later serve as spatial and temporal pivots around which other non-mandatory activities (e.g., shopping) with relatively more flexibility are scheduled. With the advent of effective telecommunication technologies, the spatial and temporal lines between work and non-work activity windows are getting blurred necessitating more nuanced design frameworks in recent times. Irrespective of the design framework adopted, most of the activity-travel choices that must be predicted within the behavioral framework are discrete in nature, that is, the traveler is faced with choice situations where one option must be picked from a set of mutually exclusive and collectively exhaustive alternatives (Train, 2003). For instance, in the commute mode choice context, the traveler chooses one travel mode from the set of car, transit, and walk/bike alternatives. So, these sub-modules are either statistical models that predict the probability of different choice outcomes or set of rules in the form of condition-action pairs that represent context-specific decision heuristics used by travelers (Pinjari and Bhat, 2011).

In the first group of ABMs that employ statistical models, the most commonly used sub-module structure is a discrete choice model that is based on the utility maximization theory of consumer choice that assumes that the traveler makes activity-travel choices that maximize his/her utility or satisfaction derived from that choice (McFadden, 2000; Bhat, 2003). For instance, in the mode choice context, every competing modal alternative is assumed to have some quantifiable utility associated with it (which is a function of the modal attributes such as travel time and travel cost as well as traveler characteristics such as income and gender). The traveler is then assumed to choose the modal alternative that maximizes his/her utility. Given that it is extremely unlikely for the analyst to know all the factors affecting the traveler's utility function, stochasticity is introduced in the utility functions leading to probabilistic predictions. Different assumptions about the nature of stochasticity underlying utility functions lead to different statistical models. For instance, the commonly used multinomial logit (MNL) and nested logit models are obtained by assuming the utility functions have a multivariate Gumbel distribution (Koppelman and Bhat, 2006). One of the critiques of utility-maximization consistent choice models is that travelers are not always perfectly rational and may make sub-optimal choices due to their limited cognitive capabilities. However, in recent times, choice models that can approximate a wide variety of decision heuristics that are not necessarily consistent with utility maximization are developed in the research community (Hess et al., 2012). In choice contexts where the underlying outcome is continuous (e.g., activity participation duration), regression and hazard durations models are also used. Examples of statistical models-based ABMs that have seen applicability in different metropolitan areas include CEMDAP (Comprehensive Econometric Microsimulator for Activity-Travel Patterns) (Bhat et al., 2004), CT-RAMP (Coordinated Travel Regional Activity Modeling Platform) (Davidson et al., 2010), TASHA (Travel/Activity Scheduler for Household Agents) (Miller and Roorda, 2003), and openAMOS (open source activity-mobility simulator) (Pendyala et al., 2012).

Rule-based ABMs are composite systems of if-else conditions which resolve activity-travel tasks that individual travelers confront daily. The underlying idea of rule-based ABMS is that the activity-travel decisions in the real world are too complex to handle within a strict utility-maximizing regimen and are based on several context-dependent heuristic rules working in tandem. However, one of the main difficulties with rule-based ABMs is that the number of if-else conditions that must be enumerated can be too large for complex decisions involved during activity generation and scheduling. In fact, most rule-based ABMs assume the generation of activity episodes as an exogenous input and primarily focus on the activity scheduling step. Also, the statistical significance of factors affecting different activity-travel decisions is not readily apparent in rule-based ABMs (Pinjari and Bhat, 2011). ALBATROSS (A Learning-BAsed TRansportation Oriented Simulation System) is an example of rule-based ABMs in which the activity-travel decisions are derived from decision trees that are trained using observed data (Arentze and Timmermans, 2004).

Hybrid ABMs that use a combination of statistical models and decision rules as well as other modeling approaches are becoming increasingly common. For instance, TASHA uses statistical models for predicting the number of activity episodes for each person along with the desired start time and duration of each episode. In the next step, the activity travel schedule is built from scratch by adjusting start times and durations to ensure feasibility. So, activity generation is not completely prior to the scheduling step because real-life schedules change, and some activity episodes may be removed as well as new activity episodes may be added during the scheduling phase (Miller and Roorda, 2003). Along similar lines, openAMOS uses statistical models for predicting activity participation and scheduling decisions in combination with the concept of space-time prisms that define the open boundaries within which the activities can take place (Pendyala et al., 2012). More recently, agent-based modeling concepts in which travelers are treated as autonomous agents who interact with their travel environment and can learn and adapt over time are incorporated in the

rule-based ABM—ALBATROSS (Arentze and Timmermans, 2004). Another example of a hybrid ABM is ADAPTS (Agent-based Dynamic Activity Planning and Travel Scheduling) which incorporates both statistical models for predicting activity-travel behavior and agent-based modeling concepts for handling dynamic interaction between the travelers and the travel environment (Auld and Mohammadian, 2009).

Survey Data Needs

The statistical models or decision rules that govern the behavior of synthetic population agents within ABMs are trained based on the observed data. To do this, extensive household travel survey (HTS) that collect detailed activity-travel diary information for a 24-hour period of a representative sample of households and individuals within those households in the study region is undertaken. The information recorded in these surveys include the activity purpose, location, departure and arrival times, duration, and means of transportation. For example, the National Household Travel Survey (NHTS) is a nationally representative periodic national survey to understand travel patterns in United States. For futuristic conditions that do not exist in the market currently (e.g., autonomous vehicles or new tolling scenarios), stated preference surveys that elicit responses from travelers under controlled choice experiments are used. In some cases, researchers develop custom-designed surveys that elicit more information on the decision process rather than choice outcomes to support the activity scheduling and conflict resolution decision rules used within ABMs (Doherty et al., 2004). In some cases, multi-day surveys that track habitual activity-travel behavior of households over time instead of a single 24-hour period are also used (Cherchi and Mohammadian, 2014).

Supplementary Modules

ABMs simulate the activity-travel patterns of every traveler residing within the study region. Therefore, a key input to ABMs are synthetic agents that are simplified microscopic representation of the actual resident population. For instance, Southern California has about 6 million households with 19 million residents. So, any ABM for Southern California should create 19 million synthetic population agents who belong to 6 million residents such that key socio-demographic characteristics of this synthetic population closely replicate those in the real-world within small geographies (such as Traffic Analysis Zones or Census Tracts). The creation of these synthetic agents (i.e., travelers) is typically handled within a supplementary module known as the “Synthetic Population Generator” (SPG). Synthetic agents are created by expanding a much smaller survey sample (e.g., Public Use Microdata Sample (PUMS) data) that includes socio-demographic information of households and their constituent people. This expansion is done iteratively such that the statistical distributions of key demographic factors in the generated synthetic population closely replicate those in the actual population while maintaining the household and population control totals (Ye et al., 2009). However, SPGs typically generate synthetic agents with only select socio-demographic factors (e.g., age, gender, and residential location). Other medium-to-long term attributes that influence activity-travel patterns (e.g., employment status, occupation industry, work location, housing tenure and type, household auto ownership, and household income) are another supplementary module because the data generated from SPGs lack variation due to expansion from a smaller sample (Pendyala et al., 2012). Another key input to ABMs is the regional land-use that is surrounding the resident population. To do this, land use models are used to predict the development patterns including the home and business locations (Waddell, 2002). Lastly, the transportation network infrastructure along with multi-modal level-of-service skims (e.g., travel times and costs) generated using traffic assignment models are also needed as input to ABMs.

Integrated Models

There are potentially strong inter-dependencies between the inputs used in the ABMs and activity-travel patterns generated by the ABMs. An obvious inter-dependency is between the network level of service (LOS) and activity-travel patterns. While activity-travel patterns at any given time depend on the network travel times and costs, it is also true that changes in the travel patterns will change the congestion patterns and associated travel times. So, there is a dynamic interaction between travel demand and transportation supply at smaller time scales. To account for this inter-dependency, ABMs are integrated with Dynamic Traffic Assignment (DTA) models in such a way that any given time the travel times between different origin-destination pairs in the activity-travel pattern are consistent with realistic network travel times (Auld et al., 2012, 2016). Along similar lines, over longer time scales, the activity-travel patterns can produce changes in the regional business and residential location patterns. For instance, transportation pricing policies can change where travel leading to residential and business relocation decisions in the long-term. Therefore, integrated land-use and transportation models that capture demand and supply interactions over medium-long term scales are being developed (Salvini and Miller, 2005; Waddell, 2011). However, the design as well as implementation of such integrated modeling systems is a challenging endeavor requiring expertise spanning multiple disciplines including transportation, urban planning, economics, human dynamics, and computer science.

Conclusion

The core idea underlying activity-based models (ABMs) is that people travel to partake in different types of activities dispersed in space and time. So, future travel demand and associated traffic conditions under different scenarios can be predicted more accurately (relative to trip-based models), if the individual decision processes underlying these activity-travel decisions can be captured better. In the past decade, ABMs have come a long way both in terms of behavioral accuracy and implementation efficacy. Recent ABMs encompass several behavioral enhancements including tour formation (i.e., where tours emerge from activity needs as opposed to fitting activities into tour templates) (Paleti et al., 2017), joint activity participation among household members (Bhat et al., 2013), and allocation and tracking of household vehicles (Hatzopoulou et al., 2007). Several metropolitan areas around the world are successfully transitioning to ABMs for developing their regional transportation plans (RTPs). Ongoing efforts are focused on (1) enhancing the policy sensitivity and forecasting accuracy of ABMs, (2) development of computationally efficient integrated modeling systems for capturing demand and supply interactions over different time scales, and (3) improving the behavioral realism of the sub-modules that govern the actions of synthetic agents within ABMs.

Introduction

Transportation systems are inherently uncertain. Travel conditions vary from day to day, both due to “supply-side” factors (incidents, poor weather, or construction work reducing capacity) or to “demand-side” factors (special events, or natural variations in travel patterns). In fact, research indicates that reliability of systems can impact travel choices just as much as their average condition (Pinjari and Bhat, 2006). This is particularly true in mode choice (many travelers are reluctant to take public transit trips, particularly those involving transfers, because of the risk of missing a connection). This uncertainty is particularly acute during disasters, when the transportation system is operating in an unfamiliar state (e.g., during evacuation, or when multiple bridges are closed due to flooding).

As a result, transportation systems need to be designed and managed considering *reliability* in addition to “typical” operating conditions. While it is impossible to eliminate all of these factors causing uncertainty, one strategy is to *provide travelers with up-to-date information on network conditions so they can make better choices*. Advanced traveler information systems (ATIS) is an umbrella term to describe such efforts to inform the public on current conditions.

ATIS has been implemented in many forms, and is growing as technology advances and becomes more accessible. Early forms of ATIS (still used today) include highway advisory radio, variable message signs, and phone lines the public can call to receive information. Later, Internet sites were created to further disseminate information. ATIS is now moving into the use of smartphones and connected vehicles to provide information. All of these forms of ATIS require information on the network condition to be gathered in some way, and ATIS thus is one part of a larger intelligent transportation system that integrates sensing and distribution of information.

While travelers are often grateful for the information provided by ATIS, it is not a panacea for addressing travel reliability. Indeed, there are cases where providing more information (or more accurate information) to travelers can actually degrade the performance of a network. Consider a message sign reporting an accident on a freeway and suggesting an alternate route. If the alternate route has a small capacity, and the accident is relatively minor, encouraging a large number of travelers to switch routes may actually cause more congestion than would have occurred in the first place. Transportation systems are complex, and simply making one part of a complex system better need not improve the performance of the larger system due to these interactions. ATIS must therefore be deployed carefully. Considerable research effort has been invested in developing strategies to forecast these impacts and design effective strategies.

The remainder of this article is organized as follows. The “Technology of ATIS” section provides an overview of the most commonly used technologies in ATIS, as well as some of the supporting technologies used to monitor the network state, and challenges in trying to *predict* a future state from present data. Section, Planning for ATIS, discusses at length several modeling tools (in particular, online shortest paths to represent how individual travelers will use ATIS, and user equilibrium with recourse to describe the collective behavior of many such travelers) that are designed to forecast the impacts that an ATIS system will have when implemented, to ensure maximum benefits to the public and avoid the type of scenario discussed in the previous paragraph. Section, Future Directions and Research Needs, concludes by discussing ongoing efforts in ATIS, and pointing specifically to research needs in this area.

Technology of ATIS

This section describes technologies, which play a role in ATIS—either in monitoring traffic conditions to generate the data for ATIS, or for reporting the data to the public. As technologies advance, the options available for these continue to grow. Therefore, the aim is

to provide an overview of the most common technologies and some emerging options, rather than to provide a comprehensive directory. A separate discussion at the end of the section highlights the differences between simply trying to observe the current state of a traffic system, and trying to *predict* its evolution over the near term. The latter problem is clearly more challenging than the former, but can play an important role in designing effective and trusted information strategies.

Technologies for Traffic Monitoring

Before travel information can be reported to the public, it must be collected in some way by the agency or organization implementing ATIS. Examples of the kind of data that can be reported in ATIS systems include:

- **Travel times** along selected corridors or roadway segments
- **Density** or **speed** of vehicular traffic (e.g., for congestion heatmaps)
- **Weather** information, such as the presence of fog or blowing snow
- Location and severity of **incidents**, **construction work**, or **roadway closures**.
- Quantity and/or location of **available parking spaces**

Although some of these data types typically require manual input (e.g., work zone locations and closures), to the extent possible ATIS systems aim to collect data automatically, possibly synthesized by human intervention, as when traffic management center employees decide what information to include in a recorded traffic information message. A number of technologies exist for continuously monitoring roadway systems to gather such information. Some examples of these technologies are:

- **Inductive loops** which detect the presence of vehicles by recording the change in impedance in a circuit when a large metallic object passes by. Inductive loops are very common on urban freeways, and can directly report vehicle flows and occupancy. By assuming a vehicle length and using traffic flow principles, these values can be converted to speed, density and other traffic variables. Installing and maintaining these devices can be difficult, because they are located within the roadway and cannot be easily accessed without closing a lane and disturbing the pavement surface.
- **Radar, infrared, acoustic, and laser sensors** can also be placed above or alongside the road to measure flows.
- **Video cameras** can be combined with image detection software to provide real-time monitoring of traffic conditions. In principle, video cameras can obtain a wider range of data than inductive loops (vehicle classification, or providing speeds and densities directly, rather than through calculation involving additional assumptions). However, they suffer from occlusion/blocking effects, and image detection algorithms are less reliable in poor weather, in darkness, or when glare or shadows obscure the image.
- **Road weather information systems (RWIS)** are automatic weather stations, recording information such as temperature, wind speed and direction, visibility, and precipitation, and communicating it to a central location.
- **Probe vehicles** can provide travel time measurements directly, rather than estimating them based on speed observations at multiple locations. Historically, official vehicles driving within the traffic stream were used as probes, with specially trained drivers instructed to travel at the average traffic speed. With advancing technology, it is possible to make use of civilian traffic to obtain equivalent data. Examples of this include using **cellular phone GPS** locations to observe speeds or travel times (many smartphones default to an “opt in” for sharing this data to a provider), or using **Bluetooth readers** to record the IDs of devices that pass the station. By locating these readers in multiple locations and matching IDs, the travel times of specific vehicles can be inferred.
- **Automated vehicle location** systems for reporting the location of public transit vehicles. GPS is currently the most common technology for this application. Alternatives (which are suitable in places with poor GPS reception) include the use of “checkpoint” systems, which receive a radio signal from a passing vehicle, or “dead reckoning” systems based on inertial measurements (acceleration, deceleration) from the vehicle to infer position over time.

Technologies for Reporting Information

After traffic data has been collected, it can be distributed to the public in a variety of modes. ATIS systems often use a combination of these modes of communication, to reach a broader segment of the population and accommodate various needs (e.g., more information can be conveyed at once through a visual message, but an audio message may be less distracting to drivers on the road). Common technologies for disseminating information to the public include:

- **Highway advisory radio**, sometimes called **traveler information stations**, broadcast a pre-recorded message on a radio frequency. A sign indicates when a message is being broadcast, commonly using lighted beacons. These devices are commonly used to report information about severe incidents or road closures.
- **Variable message signs** (also called **dynamic** or **changeable message signs**) broadcast information on a highway sign. These signs are commonly used to report corridor travel times, to report roadway incidents, or other special events.
- **Phone hotlines** can provide on-demand information to travelers, for instance playing messages pre-recorded by traffic management center employees. In the United States and Canada, the 511 number is often reserved for this purpose.
- **Websites** or **smartphone apps** can report traffic information on road closures or special events. A common feature is a “congestion heatmap,” reporting density or speed information visually through a color-coded roadway map. Some of these apps are integrated with routing software, to propose alternate routes to travelers in case of unexpected congestion.

- **SMS (texting)** systems can be used to disseminate information to travelers who have provided a mobile phone number.
- **Connected vehicles** can receive information either from roadway infrastructure (V2I) or from other connected vehicles (V2V), and can share information in turn. Onboard vehicle systems can interpret this data in various ways.
- **Transit information** can be provided at transit stops or online. This information commonly includes the estimated arrival times of upcoming buses or trains.

Predicting Traffic States

It is important to distinguish reporting *current* travel observations from reporting *predictions* of future traffic conditions. The former is easier to do; the latter may be more useful in providing route guidance: for instance, during the beginning or end of peak periods, travel conditions throughout a network may change significantly over a 30 minute trip, and anticipating these changes can lead to a better choice of routes even at the start.

There are several approaches to predicting traffic states, based on observations at a current time. Broadly speaking, these approaches can be divided into “model-based” approaches (which use some mathematical model for traffic flow over a network), and “data-driven” approaches (which rely primarily on historical data to search for patterns, using neural networks or other statistical techniques). For some recent examples of model-based approaches, see [Ji et al. \(2009\)](#) or [Kumar et al. \(2017\)](#). For examples of data-driven approaches, see [Duan et al. \(2016\)](#), [Jenelius and Koutsopoulos \(2017\)](#), or [Fan et al. \(2018\)](#).

In all cases, accuracy of the information transmitted to travelers is very important. The effectiveness of ATIS requires that travelers trust the information they receive.

Planning for ATIS

The previous section discussed a number of technological options for implementing ATIS. Planning an *effective* deployment strategy requires additional work. For instance, given a limited budget, where should a city locate variable message signs to have the greatest impact? Where should a state locate highway advisory radio transmitters to report information about weather closures? Should these devices be placed near the locations with highest traffic, the locations where travelers have the most number of viable alternatives, or somewhere else?

There are even more dramatic situations, in which providing information actually can make problems worse. That is, providing more information to more travelers does not always result in improved system performance. This is largely because transportation systems involve complex interactions among many travelers and the physical infrastructure.

In economics, an *externality* occurs when a choice made by an individual affects others who played no part in that choice. Externalities can either be positive or negative; an example of a positive externality is when a homeowner landscapes their yard nicely, in that the neighbors may also benefit from improved home values. In transportation externalities are often negative; a common example is the *congestion externality*, which arises when travelers enter an already-crowded freeway. In doing so, they cause delay to other travelers on the freeway. Another example is in turn prohibitions on busy streets—a driver waiting to turn can cause large delays to vehicles behind them who wish to continue driving through.

When externalities exist, individuals optimizing their behavior based on their own objectives may not optimize the overall system performance; that is, the so-called “invisible hand” fails to guide the system to an optimal state. This is why it may make sense to ban left turns on high-traffic arterials—even though drivers who want to turn left may suffer under such a policy, the extra distance they must travel is outweighed by the overall benefit of smoother traffic across all travelers. A more dramatic example is the Braess paradox ([Braess, 1969](#)), in which constructing a new roadway link degrades network performance for all travelers, because of congestion externalities associated with how drivers choose routes.

Analogous situations appear in ATIS deployment. Advising too many travelers to avoid an accident may overload an alternative route. A direct analogue of the Braess paradox also exists ([Ukkusuri and Patil, 2007](#)), where providing information increases the travel time for all travelers in the network.

All of these considerations underscore the need for careful planning and implementation of ATIS strategies, and subsequent monitoring and performance evaluation to ensure they are having the intended benefits. The remainder of this section discusses two categories of mathematical models, which are designed to predict the impacts of candidate ATIS strategies before implementation. The first category, discussed in Section, Modeling Individual Choices, addresses changes in behavior for *individual* travelers who receive information. The second category, discussed in Section, Modeling Collective Choices, considers the *collective* behavior of a large number of travelers who receive information. These latter models are the most useful for planning ATIS systems, using the former kind of models as building blocks.

Modeling Individual Choices

For concreteness, this section will discuss models for how drivers choose routes in the presence of real-time information. Similar models exist in the transit literature ([Rambha et al., 2016](#)), in parking ([Tang et al., 2015](#)), and other settings. In this setting, the classical assumption is that drivers choose a route with minimum generalized cost (including travel time, a monetary toll, and

possibly other factors). This route can be identified using a *shortest path* algorithm. There are very efficient algorithms that can identify such paths within seconds even on country- or continent-sized networks.

When drivers receive information *en route*, they may change their route choice in response to what they have learned. This leads to a class of *online shortest path* algorithms. Rather than generating a single path, these algorithms generate a set of *policies*, containing all of the paths the driver hypothetically might take, along with the information scenarios under which those paths would be chosen. For instance, a policy might consist of three routes (A, B, and C); where route A is followed under typical conditions, route B is followed when there is an incident at one location, and route C when there is an incident at a different location.

Online shortest path algorithms vary according to the assumptions they make regarding the nature of the information (is it local or distant? do network conditions change between when the information is learned and when the driver reaches them? is it perfect or noisy?), the underlying uncertainties in the network state (are link travel times independent or correlated?), and the behavior of drivers receiving the information (are they risk-neutral or risk-averse?). The simplest algorithms—and the most efficient—assume local information, independent link travel times, and risk-neutral travelers. These can be solved in a comparable amount of time to classical shortest paths. The most complex instances scale poorly with network size and are not yet suitable for large-scale implementation. For more details and examples of such formulations, see Polychronopoulos and Tsitsiklis (1996), Miller-Hooks (2001), Waller and Ziliaskopoulos (2002), Provan (2003), or Boyles and Rambha (2016).

Using such an algorithm, we can determine the impact of an ATIS strategy on any given traveler, by comparing the policy under ATIS to a path chosen a priori in the absence of information, or by comparing policies under different ATIS implementations. By examining the policies, one can compute the mean and standard deviation of travel time, or other reliability measures that can serve as performance metrics.

Modeling Collective Choices

Building on the models described in the previous section, we can estimate the benefits of an ATIS strategy in aggregate, over an entire population. If congestion levels are low, then the impact of one driver's route choice will not impact that of another, and one of the individual models from Section, Modeling Individual Choices, can be applied separately to each traveler, and the results summed (although aggregation by origin or destination can reduce the amount of computation; see Boyles and Waller, 2011). In such cases, there is no risk of ATIS inadvertently worsening travel conditions, because there is effectively no congestion externality.

The situation is rather different in congested networks, because of the presence of externalities. Furthermore, in congested networks drivers may not take ATIS information at face value, but rather try to anticipate how other drivers will respond to the same information. (For instance, upon receiving notification of an accident downstream, a driver seeing many other drivers exit for an alternate route may choose to remain on the freeway, anticipating that enough drivers are diverting to make the delay on the freeway manageable.) Such behavior is especially likely in situations involving experienced drivers who have traveled on the network in many different states in the past, as with regular commuters during the peak period.

In these situations, traffic assignment algorithms can be used to anticipate the effect of an ATIS system. The “base case” scenario without ATIS can be modeled using the classical formulation of the problem; see Boyles et al. (2020) for an overview of such methods. Such methods seek a solution where every traveler is assigned to a path in such a way that they cannot switch to a path with lower travel time. The extension for ATIS systems is to assign travelers to *policies* with the least expected travel time; such methods are termed *user equilibrium with recourse*. In situations where it is easy to find policies (e.g., independent link travel times and risk-neutral drivers), user equilibrium with recourse can be solved using many of the same methods used for classical assignment (Unnikrishnan and Waller, 2009; Rambha et al., 2018). Candidate ATIS deployments can then be compared based on the expected total travel time over all travelers, or using other risk measures.

It is worth noting that user equilibrium with recourse models are relatively new, and date to the last decade. The historical view is that the assumptions of an equilibrium model (first developed to reflect long-term behavior) were incompatible with the real-time perspective of ATIS (which reflects short-term fluctuations in network conditions and behavior). However, the presence of ATIS induces long-term changes in behavior—for example, one of the main arguments for providing real-time transit information is to attract passengers away from driving alone, a change in habitual mode choice. User equilibrium with recourse is designed to capture the changes in habitual behavior (as exhibited by the set of policies), as well as the short-term realization on any given day (which can be obtained by sampling the policy for a given network state and corresponding information).

Agent-based simulation is an alternative to user equilibrium with recourse. In contrast to the above models, agent-based techniques can simulate a wider variety of information strategies and driver behaviors. For instance, in situations involving unfamiliar drivers, the equilibrium assumption may be invalid, and an agent-based model can describe other behaviors. It is also easier to model correlations in the network state. However, it is harder to obtain the data necessary to calibrate agent-based models, since they often involve a larger number of parameters that need tuning, and a greater number of assumptions requiring validation.

Future Directions and Research Needs

Reliability and other effects, caused by nonrecurring sources of congestion, are major issues in transportation systems. Providing information to travelers is a relatively inexpensive strategy for mitigating these types of uncertainty. Recent technological advances make it easier to collect data on traffic conditions throughout a network, and easier to transmit this data to the public. The prospect of

providing information to a large number of travelers introduces new challenges in designing effective information strategies; it is important to anticipate how travelers will use this information, and in particular whether there may be unintended consequences that need to be addressed.

As connected and autonomous vehicle technology continues to progress, ATIS will likely see continued growth in deployment and range of applications. The range of information collected by vehicles, and that vehicles can make use of, will enable new mechanisms for addressing nonrecurring congestion; for instance, rather than simply being passive receivers of information, connected and automated vehicles may coordinate their response to network disruptions, rather than relying on an individual driver to make effective use of a limited set of information.

The prospect of ubiquitous connectivity and traveler information underscores the need for research in better understanding the behaviors, preferences, and values that travelers have regarding reliability in travel; new algorithms to make use of this emerging technological context; and new planning methods that can maximize the benefits of these new opportunities while minimizing any unintended consequences.

Understanding Demand-Responsive Transit

Demand-responsive transit (DRT) is a flexible form of public transport where vehicles adjust their service (in terms of pick-up/drop-off locations and hours of operation) based on travelers' needs rather than having fixed routes or timetables. Vehicles' capacities tend to be low, and the fleet can include taxis, vans, minibuses, or buses. DRT seeks to overcome some shortcomings of conventional transit systems in two main aspects: providing transit service in low density or poorly connected areas and providing accessibility for all travelers regardless of their necessities.

DRT services are usually presented as a complement for traditional fixed transit services. DRT services can work as feeder services that connect travelers with high-demand services (such as buses, trams, or trains). Integration with other modes (such as bike-sharing systems) has also risen as an opportunity in recent years. Alternatively, in low-density or rural areas DRT can fully replace traditional fixed transit services, aiming to provide better levels-of-service and, in some cases, lower operational costs. Empirical evidence shows that this can happen in areas where the hourly demand is around 40 passengers per mile² or less.

As urbanization levels increase worldwide, rural areas experience a decrease in population. This can lead to a decrease in level-of-services (such as reductions in the number of offered routes and their frequency) due to the high costs of maintaining low demand services. In such cases, DRT can be an attractive alternative to adjust the transit operation to its demand, offering a better level-of-service, without necessarily increase the operational costs.

DRT has also risen as an alternative for travelers with special needs (such as travelers with reduced mobility), even in high-density areas. When traditional fixed transit services do not provide an accessible service for all travelers, DRT can act as an alternative and complementary system designed for key segments of the population.

DRT are designed to serve low-demand areas and their operation is based around the flexibility on the routes and stops. Routes may be based around corridors or service areas. Stops may be predefined (i.e., fixed stops along the route), semi-flexible (i.e., combining fixed stops and on-demand stops), or fully flexible (i.e., no stops are defined in advanced). As DRT flexibility increases, access and egress times decrease, offering door-to-door service.

DRT service can be supplied by a wide variety of operators: local governments, community organizations, transit providers, and private companies, among others. This way, the level of integration and formality of DRT varies. If DRT is designed as a complement to traditional fixed transit, serving as a feeder, cooperation between both systems are key aspects in order to effectively provide a good level-of-service (e.g., by coordinating transfers and integrating fares).

Although DRT services are not a new concept (they have been proposed and discussed for many decades, mainly in developed countries), only in recent years there has been a significant increase in implementations worldwide due to technological advancements for on-line communications and management. Nowadays, travelers can easily book DRT services in real time, providing a temporal component to the DRT flexibility.

Operational Characteristics of Demand-Responsive Transit

In this section, the main characteristics of DRT, in contrast to traditional fixed transit services, are discussed. Although the implementation and characteristics of DRT systems vary, it is possible to identify different aspects of the level-of-service that they tend to provide:

1. *Connectivity*: The attractiveness of any transport mode as a travel alternative for a trip is based on the places it connects. This way, DRT should be flexible enough to serve the needs of the travelers. The route flexibility can range from fixed configurations of routes serving predetermined stops along corridors to fully flexible door-to-door services.
2. *Capacity*: DRT fleets often consider low capacity vehicles to serve low demand areas. The results of different applications around the world recommend using vehicles for 8–10 passengers. The fleet size is a key design aspect of DRT, as it determines the number of routes that can be served by the system.
3. *Hours of operation*: While DRTs flexibility is usually described in a spatial manner (adjusting routes and stops), it can also provide flexibility in a temporal manner (adjusting hours of operation). DRT services can run whenever they are needed, reducing some of the operational costs associated with running empty vehicles. Nevertheless, as in any transit system, relocation costs are always present. Moreover, DRT can be an attractive alternative for serving low demand in early/late periods that are not served by traditional fixed transit.
4. *Information and booking*: Current technologies allow for real-time bookings, as a complement for advanced booking. The former requires the travelers to wait for the service and imposes a planning challenge for the service provider, as the systems must react to real-time information. This usually leads to a higher fleet size.

Travel times are highly dependent on the flexibility of the service. As any shared mode of transport, DRT travelers are affected by each other's travel structure, particularly if the stops are flexible and the service covers an area without predetermined corridors. This way, travelers may not know in advanced how long the trip would take. Although this is true for any transit mode, where there are boarding and alighting times along the trip, the effects on DRT are increased due to deviations made along the way to serve travelers' necessities.

DRT services tend to have low frequencies and to operate without timetables. If the service runs on a corridor with predetermined stops, then travelers can access those stops and wait for the service. But in general, DRT services tend to operate with advanced and/or on-line reservations. The former can eliminate waiting times and provide a dependable level-of-service. The latter leads to a waiting times which, depending on the density of services and fleet size, can largely exceed those of traditional fixed transit services.

If the DRT system operates close to its capacity, there is a possibility that on-line reservations are declined (or at least largely delayed) and that demand is not served. The criteria for declining reservations depend on vehicle availability and deviation to pick-up or drop-off the requesting traveler. Declining a trip implies one of the most undesired outcomes of DRT operation. While denied boardings can occur on traditional fixed transit services, their higher frequency can alleviate the effects.

As DRT vehicles are smaller than traditional fixed transit, passengers ride seated. This way, comfort can be a key differentiating element as high crowding levels are nonexistent. This is particularly important for travelers with reduced mobility that highly depend on such level-of-service.

Depending on the structure of the DRT system and its integration with other modes of transport, travelers might need to transfer to reach their destinations. This happens when the DRT is designed to act as a feeder service to mass transit. Transferring does not only increase the total travel time but also can add a source of uncertainty in terms of waiting times.

DRT Applications

In this section, some implementations of DRT worldwide are described. As the characteristics and potential success of DRT systems highly depend on the context, in many cases it is not possible to compare different implementations. Nevertheless, it is possible to draw some good practices and establish some recommendations.

Australia: CoastConnect

DRT services in Australia have been designed mainly as a feeder system to connect travelers with other mass transit modes. It is aimed at commuters living in rural or low density areas and to reduce their car usage. This way, the main objective of the system is to achieve a more sustainable mobility. The system offers flexible services with door-to-door connectivity, where the trips must be booked in advanced through a smartphone application.

Austria: Go-Mobil

DRT systems in Austria offer door-to-door mobility alternatives for people in suburban and rural areas where traditional fixed transit services offer a low level-of-service or are even absent. The services are designed to be used by different segments of the population, focusing on off-peak travelers and noncommuters.

The services operate with a mixed fleet of cars, taxis, and minibuses, which accommodate to the demand, under a public private partnership scheme. Hours of operation extend until late in the night, where the availability of transport modes decreases. Trips must be booked in advance. The services are designed to offer door-to-door connectivity, while connection with other regional public transport alternatives is also possible.

Belgium: FlexiTec

DRT has been envisioned in Belgium as a last resort service for users without access to other transit alternatives, enhancing the accessibility of individuals living in poorly connected or remote areas. A key target demographic are elders and other travelers with reduced mobility that lack ease of access to regular transit and do not own a car. The majority of users are female noncommuters from households where the car is used by someone else.

Trips must be booked in advanced and the system establishes a limit of trips a traveler can make within a year, in order to manage the capacity and provide access for all. Services provide door-to-door connectivity at a significantly lower fare than other potential bus alternatives.

Bulgaria: FMS

DRT applications in Bulgaria have been targeted for tourists, in order to provide better accessibility to touristic sites, boost the economy and reduce the car usage of tourists. This focus on tourism has implied several particular characteristics of these systems: the use of electric and even horse-powered vehicles, the seasonal variation of routes and frequencies, the need to operate services with short notices, and the possibility to offer tours as part of the service.

Germany: Bürgerbus, Muldental in Fahrt and Rebus

DRT systems in Germany are diverse. While many operate in rural areas that lack connectivity through other means of public transport, other systems operate in urban areas for specific segments of the population. In general, they tend to be a complement to traditional urban and regional mass transit.

Services tend to be offered by local governments and municipalities, aimed at providing accessibility for the entire community, particularly in rural areas. Volunteer-based services are also present. While the services are available for everyone, users tend to be students, elders and people with reduced mobility, as is the case in many other countries. The fleets operate generally operate with fixed routes and stops, handling both advanced and real-time reservations.

Italy: ProntoBus

DRT in Italy has been implemented for connecting urban and suburban areas with rural areas that lack other transit services. While the system is designed to serve low density areas without alternative connectivity options, it has a special interest on travelers with reduced mobility, providing accessibility for all individuals. Services are fully flexible and allow traveling between any pairs of predetermined stops.

One of the most interesting characteristics of the DRT services is the real-time information platform provided to the users. Through a smartphone app the travelers can manage their bookings and access to information regarding the hours of operation, route availability and travel options. This interface also allows the operators to collect valuable information regarding travel structure for planning purposes.

Ireland: Ring a Link & Local Link

DRT services have been implemented in rural counties with small towns. While the counties are well interconnected, DRT provides internal services. The services are community-based and aim to reduce social exclusion. The system requires advanced booking and is mainly used by commuters and students, as well as people living in isolated places or having special needs, which now at least have a weekly opportunity for conducting activities. This way, reducing social exclusion has been one of the key drivers of DRT in Ireland.

The DRT system is comprised of different services: fixed route services that operate on a regular schedule, on-demand services that provide flexible travel options for travelers, school transport for students living in isolated places, late services to reduce drink-driving, services that connect residents with other transport hubs and social trips for members of the community.

The Netherlands: RegioTaxi

DRT services have been implemented in several regions in The Netherlands, serving low population and rural municipalities that lack other means of transport. The system aims to provide connectivity mainly in the evening, when other transit options do not operate, particularly for travelers with reduce mobility or special needs.

The services are fully flexible without predetermined routs or stops, offering door-to-door connectivity for all users. The system operates with a mixed fleet of minibuses and taxis, depending on the levels of demand. Travelers must book their trips in advanced.

Portugal: Médio Tejo

DRT services have been implemented in medium- and low-size towns in mountainous areas of Portugal, in order to promote sustainable development and enhance the connectivity for people living in low density or remote areas. No specific target demographic was defined by the operators, serving all trip purposes.

The services are operated by taxis and are fully integrated with other public transport modes, serving as feeder services. The system operates with fixed routes and stops, where trips are booked in advanced, during peak hours.

Slovenia: Sopotniki

DRT services have been implemented in Slovenian rural municipalities for elders without other travel alternatives. The service is free of charge and provides door-to-door connectivity in both directions, while accommodating for any special mobility needs. Volunteer drivers can even accompany the users on their activities, providing additional support if needed. The system is designed to provide mobility solutions for elders and avoid their social exclusion.

Spain: Shottl & Castilla y León

DRT services cover low demand origin–destination pairs in rural or poorly connected areas in different municipalities of Spain. The systems are designed to replace traditional fixed transit services due to their financial and operational restrictions. Although door-to-door connectivity is possible in some cases, the services are designed to provide connectivity to other public transport modes, acting as feeder services.

While trips can be booked in advanced, on-line booking has been implemented in recent years in some of the municipalities. Services operate with both flexible and predetermined routes and stops. A hub-and-spoke structure has been adopted in locations where a significant number of trips (mostly going to and from the urban areas) can be coordinated to reduce operational costs and increase efficiency.

Switzerland: Alpine Bus

As is the case in other countries, DRT services in Switzerland are offered where no other transit alternatives are available. The system covers mountain areas across different Swiss cantons where the population density is extremely low. But the main difference is that these services have an emphasis on tourism, the main economic activity in the areas where they operate. This way, service routes and frequencies change seasonally according to the number of tourists visiting the area.

United Kingdom: Suffolk Links

DRT services have been implemented in low density counties of the United Kingdom where connectivity is low, as no regular bus services are available. The services require advanced booking and operate 6 days a week during working hours. The DRT system provides opportunities for different travelers; while students and workers without access to car are the main demographic, the system is also used by people shopping, running errands, and even sightseeing. The system also provides access to other modes of public transport.

One of the main objectives of the DRT system is to provide sustainable travel options for the communities. Not only the vehicles are environmentally friendly in terms of emissions, but the system also reduces the necessity of households of owning a second car. The DRT services have the same fare structure than regular buses and can provide door-to-door connectivity if needed.

United States: ITNAmerica & MetroAccess

The DRT system operates as community service for elders and people with reduce mobility that lack other means of transport, in many communities across the United States where regular transit connectivity is poor or nonexistent. This way, the system provides accessibility to a segment of the population that can be otherwise excluded of society. The system is operated through privately owned vehicles and provides door-to-door connectivity for the travelers. In some cases, eligibility cards are required to use the system.

Evaluation and Discussion

Although DRT services can operate in any low demand context, most of the implementations worldwide have been in rural areas, where traditional fixed transit is absent or offers low level-of-service. The reason for such a situation is mainly an economic one: it is not viable nor convenient to operate traditional fixed transit services. While DRT can better adjust to the demand levels, providing efficient services in terms of vehicle occupancy, revenues are generally low and providers can experience losses.

The limited economic attractiveness of DRT has led to municipalities and communities to provide such services. The goal is not a private one, but a social one. DRT has proven to be a mobility solution for all segments of the population, with an emphasis on

people with reduced mobility and people without access to other means of transport. This focus on the disadvantaged is key element of DRT applications.

The social component of some DRT systems has led to free-of-charge services offered by volunteers. This is certainly based on a strong sense of collaboration within local communities, building intergenerational solidarity. Such circumstances lead to a strong support and acceptance of the DRT services within their respective areas of operation. At the same time, the involvement of the communities helps to further develop the systems.

DRT have also played a significant role in promoting sustainable transport. Many systems worldwide have set as a goal the reduction of car ownership rates. Providing a travel alternative for households instead of buying a second vehicle has helped in that sense. This can explain some mobility trends observed in many different contexts: DRT travelers tend to be noncommuters, elders, and students. Additionally, the introduction of electric vehicles to DRT fleets can further help in providing more sustainable means of travel.

Other positive externalities have been observed in some implementations of DRT. Providing late services, when traditional fixed transit does not operate, can help reduce drink-driving and provide safe mobility for vulnerable segments of the population. DRT has also shown to be an attractive alternative for promoting and easing tourism in rural areas.

Biography

Sebastián Raveau received his B.S. degree in Civil and Industrial Engineering in 2009 and his Ph.D. degree in Engineering Sciences (Transportation program) in 2014 from Pontificia Universidad Católica de Chile (PUC). He is an assistant professor at the Department of Transport Engineering and Logistics at PUC, and a researcher at the Center for Sustainable Urban Development (CEDEUS) and the BRT+ Centre of Excellence. His research interests include travel behavior, travel demand analysis and public transport systems.

Location Choice Models

What are Location Choices?

People and households choose places to live, places to work, and places and times to shop, dine, and be entertained. Firms choose where to put stores, factories, and other facilities. Public agencies choose locations for large infrastructure pieces and routes for highways.

In making location choices, decision makers weigh attributes of each potential choice in order to come to the decision that works best for them. These attributes can be inherent to a particular location (like rent, size, or attractiveness) or dependent on the relationship between that location and other locations that matter to the decision maker (like proximity to work or distance to a distribution center). Location choices are also fundamentally about time: when making a long-term choice like where to buy a house or where to put a power plant, decision makers must choose a location that meets their needs both now and in the future; when making a shorter-term choice like where to buy groceries, decision makers must choose a location that is reachable within the available time using available means of transportation.

How Do We Model Location Choices?

Two of the methods transportation researchers commonly use to understand complex spatial choices are discrete choice models and spatial optimization. While both models assume that an optimal location can be identified, they come at this question from opposite directions based on whether the researcher wants to determine what underlying criteria decision makers use to make decisions or whether they want to identify what choice should be made given a known set of criteria. In somewhat more technical terms, discrete choice models use observed or stated choices to estimate what factors underlie the latent utility function that each decision maker is seeking to optimize; in contrast spatial optimization approaches start with information about what goes into the utility calculation and choose the location that provides the greatest benefit. This chapter focuses on discrete choice modeling applied to location questions, but some of the issues presented here (particularly those relating to spatial aggregation and the modifiable areal unit problem) apply equally to spatial optimization problems.

Discrete Choice Models in a Spatial Context

Discrete choice models are used to understand and predict people's behavior when choosing a single option from a menu of two or more opportunities. These models are based on the theory that when trying to decide what to buy, where to go, or how to get there, people consider all the available options and choose the one that brings them the most benefit, measured through a latent variable called "utility" (Ben-Akiva and Lerman, 1985). Discrete choice models separate utility into a systematic component and a random component, with the systematic component of utility modeled as a linear combination of attributes of each option and individual and a set of coefficients that correspond to people's preferences. Decision makers are assumed to choose whatever option has the highest value of utility, but because the true value of the random component of utility is unknown, the models instead provide the probability of each person choosing each option based on the assumed distribution of the error term and the relative values of the systematic component of utility provided by the various choices. While there are ways in which these models may not accurately or fully represent human decision-making, they can provide useful and meaningful analysis and predictions of the choices that people make.

Location choice involves choosing a single site from a menu of options, making discrete choice models a natural fit for them, but spatial applications of discrete choice models face two problems. First, the independence of irrelevant alternatives assumption is

violated under spatial autocorrelation, necessitating either a nesting structure or an autoregressive component to account for relationships between alternatives. Second, since space can be measured at a range of scales, some degree of aggregation is in order to produce a discrete choice set. Spatial aggregation tasks must take into account the modifiable areal unit problem and ecological fallacy. Additionally, the choice sets used for location choice modeling can be quite large and differ significantly between decision makers due to variable space-time constraints and variable choices can entail very large choice sets, which presents a further challenge to modelers.

Addressing Spatial Autocorrelation in Location Choice Modeling

Conventional choice models work under the assumption of Independence of Irrelevant Alternatives (IIA), which means that an individual's relative likelihood of choosing one of two options is exclusively a function of the utility they would derive from those two options and that there is no correlation in unobserved variables between alternatives. While this assumption has been addressed in various ways throughout the field of choice modeling, it is particularly problematic in spatial choice problems because of spatial autocorrelation, the tendency of nearby observations to be similar in both measured and unmeasured ways (Anselin, 2003). Spatial autocorrelation can be made less of an issue in models if it can be accounted for by explanatory variables, but residual spatial autocorrelation violates observation independence assumptions in many families of models.

One solution to the issue of spatial autocorrelation in choice models is the nested logit, which is designed to handle some degree of correlation between alternatives by relaxing the IIA assumption (Train, 2009). In this model, nearby locations could be grouped, in essence recasting the choice into a two- (or more) step process in which the decision maker first chooses among a set of larger areas and then chooses a specific location within each one. The nested logit solution is attractive because nested models are commonly used to understand other sorts of choices, but its rigid structure produces two significant shortcomings in this context. First, this model assumes that there is no relationship between choices in different branches of the hierarchy. This is acceptable when the choices can be easily divided into spatially distinct groups, but does not work when the choices are spread continuously over an area without major divisions, as in the case of modeling housing choices as falling into different neighborhoods in a city. Second, nested models assume that a single nesting structure works for the choice sets faced by all decision makers (Pellegrini and Fotheringham, 2002; Sener et al., 2011). Cross-classified choice models that assign each option to a position within multiple separate hierarchies may be sufficient to address some of these concerns (Bhat, 2000), but in general, a model that accounts for correlations between individual pairs of options is preferable.

Spatially correlated choice models may be a preferred solution because they account for the similarity of nearby observations in a more realistic fashion. These models include a term to estimate the strength of the relationship between the utility offered by neighboring choice options. Various formulations of spatially correlated choice models have been proposed and implemented, including the Spatially Correlated Logit, which extends the nested logit framework (Bhat and Guo, 2004); the Structured Spatial Effects Model, which uses spatial weights terms in a similar way to spatial econometrics models developed from time series models (Miyamoto et al., 2004); and the Generalized Spatially Correlated Logit, which allows for neighboring locations to be modeled on a continuous scale rather than all-or-nothing (Sener et al., 2011).

A key question for spatially correlated choice models is how to think about proximity. It is convenient to model spatial relationships as binary, such that for each location there is a fixed set of neighbors determined by polygon adjacency or a K nearest neighbors search, with all other locations classified as non-neighbors. In contrast, geographers generally think of spatial relationships as a continuous variable, often according to some decay function that decreases with distance, with nearer locations more closely related and more distant points less closely related (Anselin, 2003; Goodchild, 2010; Sener et al., 2011). The decay function used can have a profound impact on the model results, making it important to choose a function that accurately represents the spatial relationships present in the data. Guo and Bhat (2007) test housing location choice models based on three different neighbor weighting schemes, one based on adjacency of census spatial units, one based on Euclidean distance, and one based on network distance, and find that using network distance is the most realistic.

Measurement Units and the Modifiable Areal Unit Problem

Aggregation of individual data points into larger spatial units is a necessary step for many sorts of geographic analysis and is particularly important for discrete choice models for home, work, and activity locations, which require limited choice sets containing meaningful and distinct spatial units. In these sorts of location choices, the actual alternatives can be thought of as specific points in space that nest within and are modeled as polygonal spatial units in order to incorporate information about the surrounding area and limit the size of the choice set for reasons of practicality.

The process of aggregating locations to areas encounters two related geostatistical problems that present a challenge to accurately modeling spatial processes: the ecological fallacy and the modifiable areal unit problem. The ecological fallacy describes the case where the value of variables aggregated by groups is inaccurately taken to reflect the value of all observations within this group. This fallacy applies to any sort of aggregation, but it can be particularly problematic for spatial/location choices since the analysis scale chosen can have a tremendous bearing on what information is available. In general, there is a tradeoff between information availability (generally greater at coarser scales) and how representative that information is (generally more at finer scales). The modifiable areal unit problem (MAUP) describes how the way in which boundaries are drawn between units can change the results of analysis, and has been identified as a potential source of bias in location choice models (Guo and Bhat, 2004). MAUP is particularly a concern in location choice modeling if the true location choices are spatially clustered or tend to be located near the edges of spatial

Figure 1 Three potential outcomes when businesses concentrated along roadways get mapped to census units. Census tracts shown in shaded colors.

units, which is discussed in more detail below. Since spatial aggregation is generally necessary for location choice modeling, care must be taken to choose spatial units that mitigate both of these effects.

Census spatial units (such as block groups and tracts) are commonly used in social and health sciences to define neighborhoods both because they are predefined and standardized and because they match the spatial resolution of other available datasets, but their size, shape, and boundaries may not be well-suited to measuring phenomena of interest to researchers (Bates, 2006; Weiss et al., 2007). Although they are designed to measure where people live, census units are often even a poor choice for delineating neighborhoods when studying housing in part because the census splits units at major roads, which assigns houses on opposite sides of the same street to separate units (Clapp and Wang, 2006).

In travel demand modeling, traffic analysis zones (TAZs) built up from census blocks are the typical spatial unit of analysis, but a variety of analytical issues arise from their use. Páez and Scott (2004) highlight two major issues with TAZs that relate to the MAUP: the scale effect, by which the same analysis can lead to different conclusions depending on the resolution of the spatial units; and the zoning effect, by which different spatial partitioning leads to a wide range of possible analytical outcomes. This casts doubts upon models that incorporate zone-level spatial relationships. Solutions to the problem of developing the “right” zoning system have been proposed that attempt to minimize some of the negative impacts of spatial aggregation, including some that focus on capturing travel within a single zone using a variety of scales (Moeckel and Donnelly, 2015; Viegas et al., 2009). Fig. 1 illustrates MAUP using business data and census tracts in Central Los Angeles.

Boundaries of these units are set based on “visible and identifiable features,” like arterial roads, which are often the site of many businesses. Commercial districts built along major roads and intersections are often split among multiple units. Fig. 1 shows three potential cases of business aggregation to tracts from an area in central Los Angeles. The first example is the best case for small commercial centers, because all the businesses are located near the centroid of a single tract. In example 2, the businesses in an area cluster along a street dividing two tracts. In example 3, a set of businesses clusters along the intersection of two major roads that divide four tracts, which means that a tract-based spatial aggregation would effectively separate those businesses by as much as half a kilometer in an area with high population density, and much more in an area with larger tracts. The bubbles on the map correspond to the search radius for destinations in each of the clusters that result from our clustering result.

Choice Sets for Location Choice Modeling

Spatial autocorrelation and the choice of spatial aggregation present problems for all modeling of spatial data, but developing comprehensive choice sets for location choice problems can present an additional difficulty that is not present in other modeling settings. Discrete choice models were originally developed to improve our understanding of mode choice, for which the range of alternatives is fairly tractable, but for location choice questions, the number of alternatives can quickly make model estimation infeasible. If measured at the scale of individual neighborhoods or census block groups, there can be hundreds of potential home locations in a major metropolitan area. Likewise potential destinations for shopping or dining can easily number in the hundreds.

The issue of choice set definition is innately tied to the choice of spatial scale and the issues of MAUP and the ecological fallacy discussed above. Modeling location choices presents a tradeoff between reality and practicality because the choice generally cannot be modeled at the finest and most realistic scale. The choice of home or destination is likely better understood as being made at the level of an individual house or a specific business establishment with information about the surrounding area as context, rather than at the level of the surrounding area with consideration for all of the opportunities available in that area, but it can be difficult to gather much usable data about specific houses or specific destinations. Given that spatial aggregation is generally necessary for data availability reasons, the question of scale becomes paramount. The ecological fallacy becomes more pronounced for larger aggregations, but it may be impractical to model choice sets with the large menu of alternatives provided by using smaller aggregations.

One proposed solution for the issue of overly large choice sets is to sample from the full choice set. Care must be taken to ensure that the sample choice set is sufficiently large and representative, and it may be necessary to apply a correction to the model to account for the subsampling (Guevara et al., 2014; Lee and Waddell, 2010; Lemp and Kockelman, 2012; Nerella and Bhat, 2004). Choice sets for destinations should also be limited by considering the temporal and mobility constraints facing the decision maker (Chen and Kwan, 2012; Wang and Miller, 2014).

Summary

Discrete choice models have been used to understand a wide range of location choices. While models for location choice encounter many of the same issues faced by choice models in other contexts, a number of problems are unique to choice modeling. Some of these issues, like the difficulty of handling the large choice sets present in many location analyses, make themselves unavoidable, whereas spatial autocorrelation, aggregation-related biases, and the links between space and time are often ignored.

Spatial autocorrelation, the tendency of nearby locations to be similar in unmeasured ways, violates assumptions about the independence of observations. In a location modeling context, spatial autocorrelation can be addressed using a nesting structure or incorporating a spatial weighting structure into the model. At minimum, it is vital to investigate spatial patterns in prediction accuracy or bias in order to determine whether further corrections for spatial autocorrelation are necessary.

The relationship between space and time (and between these and mobility) is particularly important for understanding location choices made on shorter time scales, like activity locations chosen over the course of a day. In these contexts, it's important to consider first what destinations are reachable within the available time and given the available means of transportation.

While location choices are often made at the level of an individual house or business establishment, it is generally necessary to aggregate locations into larger spatial units in order to decrease the size of the potential choice set and access data for a wider range of attributes. Using spatially aggregated data can introduce biases into models, particularly when the boundaries between units are chosen poorly or the units chosen are too large, but data availability can force the choice of a specific aggregation scale.

Introduction

Designing and managing urban transportation systems require a capability to predict the future travel that will use these systems. How far in the future depends on what decision-making processes that such forecasts aim to support. For large-scale facilities such as urban freeways or rail transit lines, 20 or 25 years in the future have been regarded as appropriate, even though such a facility may well have a longer physical and economic life. At present developing countries, especially those in Asia, are actively developing these transportation infrastructure systems at large scale in order to accommodate their rapidly expanding urban population. This is in stark contrast with the mission of the developed world, which is largely focused on travel demand management measures, as well as repairs and incremental additions to their existing and aging transportation systems. These smaller investments and operational/management plans may require forecasts for shorter time horizons, typically ranging between 1 and 5 years. Effective and efficient decisions for planning and managing these systems require an advanced evaluation framework to provide information on the distribution of impacts on travelers, employers, and public agencies. Travel forecasts are central to such a framework.

Urban transportation studies began in Detroit in 1953, then in Chicago in 1955 and later in Pittsburgh and the tristate (New York City) region, all under the leadership of Carroll and Creighton (1957). Similar studies were initiated during this period, stimulated in part by the work of Glenn Brokke, William Mertz, Walter Hansen, and others at the Bureau of Public Roads (BPR), which belonged to US Department of Commerce (Boyce and Williams, 2015). Out of these early studies emerged a travel forecasting methodology known today as the sequential procedure or the four-step procedure in the United States. These steps include:

1. *Trip generation* creates the total amount of travel per time period (hour, day) that begins and ends at each location;
2. *Trip distribution* determines the amount of travel from every origin to every destination, forming an origin–destination (O-D) trip matrix;
3. *Mode split* defines the proportion of trips by private cars, trains, buses, cycles, walking, and other modes of travel; and
4. *Traffic assignment* allocates modal trip matrices to a set of routes to determine flows on road and transit links.

Of the earlier four steps, traffic assignment lies at the core of travel forecasting and is also the focus of this paper. It determines link flows on the network, which is the goal of the entire procedure. Traffic assignment also models congestion, which has become a dominating factor in planning urban transportations systems. Importantly, it is from the representation of congestion in traffic assignment that the concept of equilibrium and feedback loop first originates.

The remainder of this paper is organized as follows. First, we summarize the basic definitions, notation, and assumptions that are common to travel forecasting and network equilibrium modeling. Then in Section “The Four-Step Procedure With Feedback” we review the four-step procedure for travel forecasting and introduce the concept of “feedback.” Section “User Equilibrium Traffic Assignment” presents the basic equilibrium model for the traffic assignment problem. Section “Combined Equilibrium Models” introduces the so-called combined models to integrate the last three steps in the four-step procedure into a single model. Essentially, combined models replace the external feedback with internalized interactions between destination, mode, and route choices. The last section concludes this paper with a discussion of future research.

Problem Setting

Consider an urban region divided into small, relatively homogeneous zones. Zone size varies with the density of development, so that activity levels per zone are relatively similar. These zones will be referred to as traffic analysis zones (TAZ) hereafter. Urban

activities in TAZs are described in terms of: (1) residential population and households; (2) employment, education (primary, secondary, and higher), or day care; and (3) shopping, personal and business services, recreation, etc. Facilities that support urban activities consist of land and buildings for (1) residences, (2) workplaces, (3) schools, (4) shopping and service centers, and (5) parks and recreational facilities.

Travel occurs on two types of transportation systems or modes, namely roadway and public transport, which consist of three elements: equipment, infrastructure, and control policy. The roadway system is characterized by private vehicles (equipment), ways for driving-biking-walking (infrastructure), and traffic control system (control policy). For public transport, the three elements are, respectively, bus or train, roadway or railway, and operations plan. The roadway systems are represented as networks of nodes and links, and for public transport, routes of scheduled services. Service characteristics of links depend on fixed parameters related to physical characteristics such as (1) length, number, and width of lanes by type including bikeways and walkways; (2) grade; (3) public transport station spacing and vehicle performance; (4) control and operations plans, for example, speed limits, signal settings, road tolls; and (5) service frequencies, operating speeds, and public transport fares. Other variables are related to travel flows (demand), which also determine service characteristics. These include flows of cars, trucks, bikes, and pedestrians and public transport boarding and alighting at stops per unit time. Taken together, these variables determine the performance characteristics of individual links, conceptualized as:

$$\text{Link travel time} = f(\text{flows} | \text{fixed vehicle/way characteristics, and operations plans}).$$

The earlier relationship is commonly known as a cost-performance function or *link performance function*. It is worth noting here that such a performance function represents traffic congestion at an aggregated level for the average condition in a relatively long analysis period. It is not intended to capture the dynamic evolution of traffic flow.

Travel between daily activities (e.g., residing, working, eating, shopping, schooling, recreating) may be described in terms of pairs of activities linked by trips. According to the activity purpose, a *trip* may be classified as a home-work trip, a work-shop trip, a shop-home trip, and so on. In the trip-based approach, individual trips are aggregated by purpose and forecast as separate groups. Whether travel occurs by private car (either alone or with others), by public transport, bike, or walking, depends on the availability of modes, their relative service times and monetary costs, as well as intangible factors like comfort and convenience.

The timing of travel during the day depends on constraints imposed by activity schedules and the prevailing travel conditions in the transportation systems. Trips occurring in a 24-hour weekday are typically aggregated into several periods, such as the morning peak commuting period or the off-peak period. A transformation is usually needed to convert observed trips corresponding to a specific departure or arrival time into flows in each period (measured by person/unit time).

For transportation systems planning, facility design, operations planning, or conformance with air quality regulations, forecasts of the following variables are required for each scenario of transportation system/activity pattern:

1. Flows of private cars, trucks, bikes, pedestrians and public transport vehicles on the road network by morning and evening peak commuting periods, and for longer periods when travel conditions are relatively stable;
2. Flows of persons on the public transport network by sub-mode and by time period; and
3. Flows of persons from origin zone to destination zone by private vehicles and public transport and by time period.

A capability to examine changes in these flows in response to changes in network layout, capacity and service attributes, monetary costs (e.g., fuel, tolls, fares, parking fees), and changes in zonal activity levels is an essential requirement for planning urban transportation systems.

The Four-Step Procedure With Feedback

An early prototype of the four-step procedure was developed in Detroit and Chicago transportation studies in 1950s. The procedure consists of three parts: estimating trips generated from and attracted to each TAZ according to land use, predicting flows between each O-D zone pair, and transforming O-D flows into predicted traffic flows on links in each major type of transportation network. At the time, such studies primarily concerned roads, so only travel by car was forecasted. The procedure was soon extended to include travel by transit, and the “splitting” of those trips by mode, but nonmotorized travel was ignored.

Estimating the number of trips from land use became *trip generation* (Fig. 1) and is typically based on linear regression methods. Predicting future O-D flows was performed by a *trip distribution* procedure. Growth factor methods were initially employed for trip distribution, but they were later replaced by the concept of spatial interaction between points separated by travel distance or travel time, which were analogous to the gravity law of spatial interaction, and indeed became known as the *gravity model*. Early innovators in trip distribution modeling were Voorhees (1955), who introduced the empirical gravity concept into urban travel forecasting, and Schneider (1959), who derived and implemented an *intervening opportunities* model. *Mode choice* was initially based on the so-called diversion curves, until replaced by more sophisticated discrete choice models. The last step, that is, loading O-D flows onto the transportation networks, came to be known as *traffic assignment*.

Even in the 1950s, the creators of the early sequential procedure realized that an iterative solution process—which they termed *feedback*—is required for their method. They noted that (1) O-D flows are typically modeled as a function of travel time in trip distribution, and, when assigned to the road network, result in link flows and link travel times; but (2) these link times determine the

Figure 1 The four-step procedure with feedback.

travel times between any O-D pair, which in turn affect O-D flows. Thus, a feedback from traffic assignment to trip distribution is required. Since mode choice also employs the O-D travel times from traffic assignment as inputs, it too should receive a feedback. The feedback loops must be repeated to reach equilibrium and consistency between the input data and the final results. That is, the O-D travel times fed into the trip distribution or mode choice model should produce the same travel times after the procedure runs its course. However, a key question regarding the feedback scheme is whether or not it converges to a stable equilibrium when iterated. Guaranteeing the convergence poses a significant theoretical challenge that calls for different modeling approaches. We will discuss such an approach in Section “Combined Equilibrium Models.”

User Equilibrium Traffic Assignment

John Wardrop (1952), a British traffic scientist, proposed the following criterion to describe traffic flows on a network:

“The journey times on all routes actually used are equal, and less than those which would be experienced by a single vehicle on any unused route. . . . (this) criterion is quite a likely one in practice, since it might be assumed that traffic will tend to settle down into an equilibrium situation in which no driver can reduce his journey time by choosing a new route.” (Patriksson, 1994, p. 31)

The first sentence is now known as Wardrop’s first principle of *user equilibrium* (UE). By “routes actually used” Wardrop meant the routes used to travel from a given origin to a given destination, or an O-D pair. If routes consist of sequences of links, then route costs may be defined as the sum of the link costs along the route. Since link costs depend on link flows through the link performance function, and each link may serve many routes connecting different O-D pairs, identifying the route costs that satisfy Wardrop’s principle involves solving the route choice problem simultaneously for the entire network of many O-D pairs.

Link flows have units of vehicles/hour (vph), so route flows and O-D flows also have units of vehicles/hour or persons/hour. The resulting route choice model is a steady-state (or static) flow model that does not consider the physical movement of an individual trip from its origin to its destination. Rather, O-D flows occur with corresponding flows on the links of each used route. This formulation leads to a relatively simple concept of congestion: steadily flowing vehicles traveling at speeds determined by link performance functions. Clearly, it cannot accurately capture dynamic traffic phenomena, such as queuing behind bottlenecks, or delays propagating from one link to another.

The UE link flows and costs, and a set of route flows, corresponding to fixed O-D flows may be determined by solving the following constrained optimization problem (Beckmann et al., 1956; Sheffi, 1985, p. 60).

$$\min z(f) = \sum_{a \in A} \int_0^{x_a} c_a(w) dw \quad (1)$$

subject to:

$$\sum_{k \in K_{rs}} f_k^{rs} = q_{rs}, \quad \forall r \in R, s \in S, \quad (2)$$

$$f_k^{rs} \geq 0, \quad \forall k \in K_{rs}, r \in R, s \in S, \quad (3)$$

$$\sum_{r \in R} \sum_{s \in S} \sum_{k \in K_{rs}} f_k^{rs} \delta_{ak}^{rs} = x_a, \quad \forall a \in A, \quad (4)$$

where:

- x_a = flow of all vehicles on link a (vph),
- $c_a(x_a)$ = generalized travel cost function for link a , a nondecreasing function of link flow x_a ,
- f_k^{rs} = flow of vehicles on route k in the set of all routes K_{rs} connecting O-D pair r and s (vph),
- q_{rs} = exogenous flow of vehicles between O-D pair r and s (vph),
- $\delta_{ak}^{rs} = 1$, if link a belongs to route k connecting O-D pair r and s , and 0 otherwise,
- R, S = sets of origin and destination zones, respectively, and
- A = set of links in the network.

The unknown variables are vehicle route flows $f = (f_k)$. The vehicle link flows (x_a) are defined in terms of the route flows, through the exogenous link-route correspondence matrix (δ_{ak}^{rs}) .

The optimality conditions for the earlier problem may be stated as:

$$\sum_{a \in A} c_a(x_a) \delta_{ak}^{rs} - u_{rs} \geq 0, \quad \forall k \in K_{rs}, r \in R, s \in S, \quad (5)$$

$$f_k^{rs} \left(\sum_{a \in A} c_a(x_a) \delta_{ak}^{rs} - u_{rs} \right) = 0, \quad \forall k \in K_{rs}, r \in R, s \in S, \quad (6)$$

where u_{rs} is a dual variable associated with the conservation of flow constraint defined on the exogenous O-D flow q_{rs} . Conditions (6) may be interpreted as follows for O-D pair rs :

$$f_k^{rs} > 0 \Rightarrow c_k^{rs} = u_{rs}, \quad \forall k \in K_{rs}, \quad (7)$$

$$f_k^{rs} = 0 \Rightarrow c_k^{rs} \geq u_{rs}, \quad \forall k \in K_{rs}, \quad (8)$$

where c_k^{rs} is the travel cost on route k , the sum of the costs of the links comprising route k . Hence, every used route between an O-D pair rs has a (minimum) generalized travel cost equal to u_{rs} , and no unused route has a lower travel cost. Thus, this formulation corresponds to Wardrop's first principle.

If the generalized cost functions are strictly increasing with link flows, then the objective function in Eq. (1) is strictly convex, guaranteeing that the solution is unique in the link flows. However, the solution is not unique in the route flows, since the objective function is not strictly convex with respect to the route flows in general. The earlier formulation also requires each link performance function be *separable*, that is, it depends only on the link's own flow. If there are cross-link interactions, the applicability of the formulation depends on whether or not such interactions are *symmetric*, namely each link performance function depends on a specified vector of link flows such that the effect of a change in link a 's flow on link b equals the effect of a change in link b 's flow on link a for all links specified in the cost function. Models not exhibiting such symmetries are called *asymmetric*, and they can no longer be formulated as a minimization problem. Instead, more general formulations, such as those based on variational inequality or nonlinear complementarity problems, are often used.

Modeling route choice on a public transport network is generally more complex. An important difference between roadway and transit systems is that, whereas travel by car generally can begin on demand, travel by transit begins when the transit vehicle (bus, train) arrives at the point of service or service node (bus stop, station). Hence, transit riders incur waiting and transfer times that depend on the service timetable and the arrival times of passengers at the service node. These waiting times contribute to a different type of stochastic attribute than the one found in route choice by car drivers.

Generally, the objective of each transit rider is assumed to minimize his or her generalized travel cost, a weighted linear function of in-vehicle travel time, waiting and transfer times, and fare. Since the waiting and transfer times are not deterministic but depend on the service frequency and passenger arrival pattern, each passenger's objective is to minimize the expected generalized travel cost. If transit services are frequent, it is reasonable to assume that travelers arrive at their service nodes randomly with respect to the service schedule and take the first vehicle belonging to the set of "desired" transit lines. This set of lines and the rules that allow the traveler to reach his/her destination is usually called a *strategy* (Spiess and Florian, 1989). Developing strategy-based (or hyperpath-based) transit assignment models remains an active research area, and a particular challenge here is to account for congestion and crowding effects, which exhibit very different characteristics than those found in roadway systems. These more complex transit route choice models are not considered in combined equilibrium models discussed in the next section.

Combined Equilibrium Models

Combined Mode and Route Choices

If travel choices are viewed as a hierarchy, then route choice would seem to fall naturally at the lowest level. Route choices are specific to each transportation mode and may vary in every trip in response to current travel conditions. The choice of mode may be hypothesized to be the next higher choice in this hierarchy. Mode choices may be made on a daily basis, assuming a car is available. Choice of cycle and walking may also be considered, if available as options. Note that the representation of choices as a hierarchy does not imply that choices are made sequentially.

Instead of linking route and mode choices through a feedback as described in Fig. 1, a combined modeling approach attempts to integrate these choices in a same optimization problem (Boyce and Bar-Gera, 2003). To begin, the deterministic car route choice model is extended to include choice of mode. Let us assume that only two modes are considered: car and transit; the transit between any O-D pair has a fixed, flow-independent cost γ_{rs} , and transit vehicles do not impact road networks. Then, the aforementioned route choice problem can be generalized to the following combined mode and route choice problem:

$$\min z(\mathbf{f}, \mathbf{q}^t) = \sum_{a \in A} \int_0^{x_a} c_a(w) dw + \sum_{r \in R} \sum_{s \in S} q_{rs}^t \gamma_{rs} \quad (9)$$

subject to:

$$\sum_{k \in K_{rs}} f_k^{rs} + q_{rs}^t = q_{rs}, \quad \forall r \in R, s \in S, \quad (10)$$

$$\sum_{r \in R} \sum_{s \in S} \sum_{k \in K} f_k^{rs} \delta_{ak}^{rs} = x_a, \quad \forall a \in A, \quad (11)$$

$$f_k^{rs} \geq 0, q_{rs}^t \geq 0, \quad \forall k \in K_{rs}, r \in R, s \in S, \quad (12)$$

where q_{rs}^t denotes the flow using the transit mode between O-D pair rs . This formulation seeks to find the allocation of exogenous O-D flows to the two modes, and within the car mode to routes, so as to minimize an objective function constructed according to desired equilibrium conditions. Because car route flows should satisfy the UE conditions, the total cost of car travel is not minimized; rather, the sum of the integrals of the links cost functions is retained. The optimality conditions pertinent to route and mode choice include Eqs. (10–12) and:

$$q_{rs}^t (\gamma_{rs} - u_{rs}) = 0, \quad \forall r \in R, s \in S. \quad (13)$$

To interpret these conditions, note that the UE costs of the used car routes not only determine the O-D cost, but also determine whether any of the fixed cost transit mode has sufficiently low costs to be used: if $u_{rs} < \gamma_{rs}$, then $q_{rs}^t = 0$ (no one uses transit). If $u_{rs} = \gamma_{rs}$, then the O-D cost of transit and car are equal, and use of transit may occur. If $u_{rs} > \gamma_{rs}$, then all O-D flow occurs by transit, and no one uses car. That is, either there is transit flow or the transit cost sets a maximum level for the car costs for each O-D pair. Hence, the solution is “all-or-nothing” with respect to mode choice.

In survey data, one often observes travel by two or more modes (car, transit, cycle, or walk) between many O-D pairs. Therefore, the formulation of the mode and car route choice model as a deterministic optimization problem, while instructive, is unrealistic. The relaxation of this deterministic formulation can be achieved through the addition of a modal dispersion constraint. A function representing modal dispersion may be imposed to make mode choices more dispersed than the UE level, that is, some choices are allocated to higher cost modes. For example, the mode split between each O-D pair may be predicted using the logit model as follows:

$$q_{rs}^t = \frac{q_{rs} e^{-\theta \gamma_{rs}}}{e^{-\theta \gamma_{rs}} + e^{-\theta u_{rs}}}, \quad (14)$$

where θ is a dispersion parameter. The earlier equation can be rearranged as:

$$u_{rs} = \gamma_{rs} + \frac{1}{\theta} \ln \frac{q_{rs}^t}{q_{rs} - q_{rs}^t}. \quad (15)$$

If we view the transit line as a special link between the O-D pair with the travel cost defined by $\gamma_{rs} + \frac{1}{\theta} \ln \frac{q_{rs}^t}{q_{rs} - q_{rs}^t}$, then the combined mode choice/traffic assignment problem can be reformulated as follows:

$$\min z(\mathbf{f}, \mathbf{q}^t) = \sum_{a \in A} \int_0^{x_a} c_a(w) dw + \sum_{r \in R} \sum_{s \in S} \int_0^{q_{rs}^t} \left(\gamma_{rs} + \frac{1}{\theta} \ln \frac{w}{q_{rs} - w} \right) dw \quad (16)$$

subject to

$$\sum_{k \in K_{rs}} f_k^{rs} + q_{rs}^t = q_{rs}, \quad \forall r \in R, s \in S, \quad (17)$$

$$\sum_{r \in R} \sum_{s \in S} \sum_{k \in K_{rs}} f_k^{rs} \delta_{ak}^{rs} = x_a, \quad \forall a \in A, \quad (18)$$

$$f_k^{rs} \geq 0, \quad \forall k \in K_{rs}, r \in R, s \in S. \quad (19)$$

The second term in Eq. (16) is interpreted as a dispersion term for mode choice.

Combined Model of Destination, Mode, and Route Choice

The combined mode and route choice formulation can be further extended to include an O-D dispersion function in the same manner as described earlier (Boyce and Daskin, 1997). In the version presented here, constraints are added to the mode and route choice formulation to derive a classical gravity trip distribution model. These constraints consist of origin and destination constraints and another function representing dispersion of trips to higher cost destinations, separately from the modal dispersion constraint. We can similarly convert these constraints into a dispersion term (as in Eq. (15)) and add it into the objective function, which lead to the following formulation:

$$\begin{aligned} \text{Min } z(\mathbf{f}, \mathbf{q}) = & \sum_{a \in A} \int_0^{x_a} t_a(w) dw + \frac{1}{\theta_1} \sum_{r \in R} \sum_{s \in S} q_{rs} (\ln q_{rs} - 1) \\ & + \frac{1}{\theta_2} \sum_{m \in \{a, t\}} \sum_{r \in R} \sum_{s \in S} q_{rs}^m (\ln q_{rs}^m - 1) + \sum_{r \in R} \sum_{s \in S} \gamma_{rs} q_{rs}^t \end{aligned} \quad (20)$$

subject to:

$$\sum_{k \in K_{rs}} f_k^{rs} = q_{rs}^a, \quad \forall r \in R, s \in S, \quad (21)$$

$$\sum_{m \in \{a, t\}} q_{rs}^m = q_{rs}, \quad \forall r \in R, s \in S, \quad (22)$$

$$\sum_{s \in S} q_{rs} = O_r, \quad \forall r \in R, \quad (23)$$

$$\sum_{r \in R} q_{rs} = D_s, \quad \forall s \in S, \quad (24)$$

$$\sum_{r \in R} \sum_{s \in S} \sum_{k \in K_{rs}} f_k^{rs} \delta_{ak}^{rs} = x_a, \quad \forall a \in A, \quad (25)$$

$$f_k^{rs} \geq 0, \quad \forall k \in K, r \in R, s \in S, \quad (26)$$

$$q_{rs}^m \geq 0, \quad \forall m \in \{a, t\}, r \in R, s \in S, \quad (27)$$

where q_{rs}^a and q_{rs}^t represent the demand for car and transit modes, respectively, and θ_1 and θ_2 are the dispersion parameters corresponding to trip distribution and mode choice, respectively. Let u_{rs} , k_{rs} , μ_r , λ_s denote the multipliers of the constraints (21), (22), (23), (24), respectively. Then, the optimality conditions pertinent to mode choice and trip distribution are stated as follows:

$$\frac{1}{\theta_1} \ln q_{rs} + k_{rs} - \mu_r - \lambda_s = 0, \quad \forall r \in R, s \in S, \quad (28)$$

$$\frac{1}{\theta_2} \ln q_{rs}^a + u_{rs} - k_{rs} = 0, \quad \forall r \in R, s \in S, \quad (29)$$

$$\frac{1}{\theta_2} \ln q_{rs}^t + \gamma_{rs} - k_{rs} = 0, \quad \forall r \in R, s \in S. \quad (30)$$

Eqs. (29) and (30) lead to:

$$q_{rs}^a = e^{\theta_2(k_{rs} - u_{rs})}, \quad (31)$$

$$q_{rs}^t = e^{\theta_2(k_{rs} - \gamma_{rs})}. \quad (32)$$

The modal flows q_{rs}^m are constrained to sum to the O-D flow by the mode conservation of flow constraint. Thus, inserting q_{rs}^m into Eq. (22) yields:

$$e^{\theta_2 k_{rs}} = \frac{q_{rs}}{e^{-\theta_2 u_{rs}} + e^{-\theta_2 \gamma_{rs}}}, \quad (33)$$

from which the multiplier k_{rs} can be derived as:

$$k_{rs} = \frac{1}{\theta_2} \ln q_{rs} - \frac{1}{\theta_2} \ln(e^{-\theta_2 u_{rs}} + e^{-\theta_2 \gamma_{rs}}). \quad (34)$$

Inserting (34) back to (31) and (32) leads to the logit mode choice:

$$q_{rs}^a = \frac{q_{rs} e^{-\theta_2 u_{rs}}}{e^{-\theta_2 u_{rs}} + e^{-\theta_2 \gamma_{rs}}}, \quad (35)$$

$$q_{rs}^t = \frac{q_{rs} e^{-\theta_2 \gamma_{rs}}}{e^{-\theta_2 u_{rs}} + e^{-\theta_2 \gamma_{rs}}}. \quad (36)$$

Furthermore, by replacing k_{rs} in Eq. (28) with (34) we have:

$$\frac{1}{\bar{\theta}} \ln q_{rs} - \Gamma_{rs} - \mu_r - \lambda_s = 0, \quad (37)$$

where $\bar{\theta} = \frac{\theta_1 \theta_2}{\theta_1 + \theta_2}$ and $\Gamma_{rs} = \frac{1}{\bar{\theta}} \ln(e^{-\theta_2 u_{rs}} + e^{-\theta_2 \gamma_{rs}})$ may be interpreted as the total disutility associated with both modes for the O-D pair rs . An expression for the O-D flow q_{rs} can then be derived from (37) as:

$$q_{rs} = e^{\bar{\theta}} (\Gamma_{rs} + \mu_r + \gamma_s). \quad (38)$$

By substituting q_{rs} into Eqs. (23) and (24) we have:

$$\begin{aligned} e^{\bar{\theta}} \mu_r &= \frac{O_r}{\sum_{l \in S} e^{\bar{\theta}} (\lambda_l + \Gamma_{rl})} \equiv A_r O_r, \\ e^{\bar{\theta}} \lambda_s &= \frac{D_s}{\sum_{l \in R} e^{\bar{\theta}} (\mu_r + \Gamma_{ls})} \equiv B_s D_s, \end{aligned} \quad (39)$$

which allows us to rewrite q_{rs} in the form of the conventional gravity model as:

$$q_{rs} = A_r B_s O_r D_s e^{\bar{\theta}} \Gamma_{rs}. \quad (40)$$

The earlier formula predicts that the flow between an O-D pair increases with the product of the total trip generation and attraction, and decreases with the disutility associated with travel between the O-D pair. Alternatively, we can also express q_{rs} only using the first relationship in Eq. (39), that is,

$$q_{rs} = \frac{O_r e^{\bar{\theta}} (\lambda_s + \Gamma_{rs})}{\sum_{l \in S} e^{\bar{\theta}} (\lambda_l + \Gamma_{rl})}. \quad (41)$$

Then, by substituting the O-D function for q_{rs} into the O-D-mode function for q_{rs}^m , the combined O-D-mode function may be stated as:

$$\begin{aligned} q_{rs}^a &= \frac{O_r e^{\bar{\theta}} (\lambda_s + \Gamma_{rs})}{\sum_{l \in S} e^{\bar{\theta}} (\lambda_l + \Gamma_{rl})} \cdot \frac{e^{-\theta_2 u_{rs}}}{e^{-\theta_2 u_{rs}} + e^{-\theta_2 \gamma_{rs}}}, \\ q_{rs}^t &= \frac{O_r e^{\bar{\theta}} (\lambda_s + \Gamma_{rs})}{\sum_{l \in S} e^{\bar{\theta}} (\lambda_l + \Gamma_{rl})} \cdot \frac{e^{-\theta_2 \gamma_{rs}}}{e^{-\theta_2 u_{rs}} + e^{-\theta_2 \gamma_{rs}}}. \end{aligned} \quad (42)$$

The earlier result can be interpreted as a two-level nested logit choice model on the part of the traveler (Fig. 2), where the first layer determines the destination and the second determines the mode.

Figure 2 Interpretation of the combined model as a two-level nested logit choice model.

Future Research

Despite more than 60 years of research on urban transportation network equilibrium, many problems remain unsolved, and practice lags increasingly behind research knowledge. Research problems may be broadly classified according to travel choices, network representation, network design, and solution procedures, among others.

1. Until now, the modeling of travel choices has mainly followed the trip-based paradigm in practice. Increasingly, travel demand modelers view travel in terms of daily tours or daily activities. Generally, prediction of tours or activities has been approached from a micro-simulation point of view. Yet, the simulation-based approach encounters many analytical and practical challenges—computation resources, data requirements, calibration issues, to just name a few—that have so far hindered its broad adoption.
2. The representation of travel cost functions in network equilibrium models has advanced little beyond the original separable formulation of Beckmann. Although asymmetric models can be formulated as variational inequality problems, the lack of uniqueness of solutions has discouraged serious efforts to investigate this approach further. The paradigm shift to a dynamic representation of the underlying physical world has been pursued with enthusiasm by both researchers and practitioners in the past 3 decades. Yet, the real impact of this movement on the urban travel forecasting practice remains unclear.
3. Another problem that has received little attention, at least in practice, is transportation network design. In a combinatorial sense, the network design problem is intractable because of its large size. One way to address this challenge is to choose from a set of alternative designs generated using a systematic and semiautomated approach. Such a method would require an ability to distinguish among the merits of closely related scenarios. Given the recent advances in high-performance solution algorithms to network models, this capability may now be achievable. Other approaches are possible, however, such as *continuous approximation* (an example is the spacing of freeways in a grid, as was considered early in the history of this field).
4. Although practitioners are required by government regulations in the United States to solve their sequential travel forecasting procedures in a way that achieves an internal consistency of travel costs, there is no general agreement on how this should be done. No practitioner or software developer has described, tested, and demonstrated that one procedure is best among alternatives for the complex models typically applied in practice. Moreover, the errors introduced in forecasts that do not achieve consistency remain unknown. This relatively straightforward research problem should be tackled.
5. Academic interest in the solution of combined model formulations of travel choice has influenced travel forecasting practice, but only to a limited extent. Except for Santiago, Chile, combined models have rarely been applied in practice. The formulation of a combined model clearly enhances the understanding of the challenges facing the practitioner in solving the sequential procedure. Few practitioners, however, seem equipped by their training or mathematical ability to gain from insights from these formulations. Moreover, software developers have not incorporated tools in their software systems to facilitate the application of this approach. Based upon past experience, they will not do so until interest among practitioners strongly induces them to proceed.

Pursuit of the earlier research agenda requires a knowledge of optimization methods, computer skills, data, and perseverance. Many similar problems could be identified, especially from the viewpoint of other perspectives. For those so inclined, the journey will be challenging, but always interesting, and hopefully rewarding.

Introduction

Geographic information systems (GIS) refer to computer systems for capturing, storing, managing, analyzing, and presenting geographically referenced data. Transportation modeling has an inherent geographic component in it as it aims to characterize and predict (using mathematical and statistical tools) the movement of people and goods over space and time. While GIS and transportation modeling have been developing in their respective fields separately, the geographic focus of GIS and the geographic nature of transportation make the use of GIS in transportation modeling both a logical choice and a motivation for enhancement (Lewis, 1990; Waters, 1999; Loidl et al., 2016). Public agencies and private consulting firms in transportation have adapted GIS widely for the interest of sharing and managing data sources, supporting transportation modeling and plan-making, and informing public engagement and investment decisions (e.g., USDOT, 2016).

GIS may apply to transportation modeling in different stages of modeling work, including data assembling from multiple input sources, calibration of model parameters and search for best-fit model specifications, and communication of modeling results with the public and policy makers (Slavin, 2004). There are generic commercial GIS packages, for example, ArcGIS developed by ESRI (2019). Institutional or private sector users may customize the system to develop extensions to the built-in functions and modules for specific applications. Specialized GIS packages, for example, TransCAD (Caliper, 2019), PTV (PTV Group, 2019), and CUBE (Citilabs, 2019), offer fully integrated procedures of transportation modeling in addition to the basic GIS data processing and visualization functions. GIS scholars and transportation professionals have also developed GIS applications for modeling specific topics of transportation interest, for instance, accessibility modeling and land use-transportation integrated (LUTI) models. These GIS applications may operate as stand-alone programs or may be loosely coupled with existing GIS packages.

This chapter introduces the use and value of GIS in transportation modeling. The rest of the chapter includes four parts. Part 1 explains how the topological data structure underlying vector GIS design fits well the needs of data handling for transportation modeling. Part 2 describes GIS applications to the standard procedures of four-step transportation models and to specific transportation modeling interests, including accessibility modeling and LUTI modeling. Part 3 highlights the visualization feature of GIS and illustrates how geo-visualization has contributed to advancing transportation modeling. Lastly, Part 4 discusses the potential of and challenges to GIS in and for transportation modeling amid rapid development of new information and communications technologies (ICTs) and burgeoning new markets for shared economy and shared mobility as well as autonomous/driverless vehicles (AV/DV). The chapter ends with concluding remarks.

GIS Data Integration and Handling

The fundamental concern of transportation is the movement of people and goods. Transportation modeling takes a quantitative approach to assess the condition of people and goods movement in the existing transport system, predict the system performance under assumed future conditions, and identify needs for policy interventions. Hence, adequate data input is crucial to transportation modeling. GIS presents a capable tool to integrate spatial and nonspatial data in a unified platform for enhanced transportation modeling.

Typically transportation modeling utilizes three types of data (Cambridge Systematics, Inc., et al., 2012): (1) socioeconomic and demographic data that typically exist in aggregate areal units, for instance, traffic analysis zones (TAZs), zip codes, and counties; (2) infrastructure and system network data that display linear features, for instance, highway and street segments, transit routes, and pipelines, or in point format, for instance, street intersections as network nodes, transit station or stop placements, and locations of traffic incidents; (3) performance data such as vehicle flows, transit ridership, congestions, accidents, and emissions that can be reported in various

geographic locations and spatial scales. Data for model validation are also critical to transportation modeling. Quality transportation modeling relies on quality data input from various sources. It is the variety of input data in formats, metrics, and standards that creates a start-up challenge before essential modeling work begins. GIS integrates spatial and nonspatial data from various sources through the application of a topologically referenced relational data structure (Galdi, 2005; Longley et al., 2011).

Essentially GIS represent spatial features in three basic types of data objects (Chang, 2018): point (node), line (arc), and polygon (area). Depending on the spatial scale, a geographic feature can be represented in different type of features. For example, a city may appear as a point in the large scale of national map layer. In a detailed map scale, the city may become a polygon object to show the area of city limits. The three basic types of objects are geographically referenced and topologically encoded: points (nodes) are defined by their geographic coordinates (longitude and latitude) through geographic projections; lines are vectors defined by the starting and ending points (nodes); multiple vector lines define polygons (areas). Each of the spatial objects has its unique data table to record the spatial attributes, for instance, the X-/Y-coordinates of points (nodes), the IDs of the From-/To-nodes and the linear length of lines, and the area of polygons (Fig. 1). The three basic types of objects are interrelated as defined by their topological

Figure 1 Illustration of topological representation of selected city blocks near the state capital of Texas. Source: Author.

relationship (Hoel, 2009). This data topology allows for representation and examination of spatial relationship within and between these objects in terms of dimensionality, adjacency, connectivity, contiguity, and containment.

The relational database structure also enables the attribute tables for the spatial objects to be related to auxiliary data tables, for example, information on the name, capacity, and service hours of a train station attached to the point where the station is located, bus frequency and service capacity information attached to the attribute tables of the lines with transit routes; total population and employment for census tracts or TAZs related to polygon features (e.g., zipcode areas and TAZs). Data integration achieved by GIS enables cross-data source referencing, integrating data between spatial and nonspatial and different spatial data types of the same spatial layer, or datasets from different spatial layers. For instance, for transit catchment area analysis, GIS's built-in tools allow different ways to perform spatial buffering analyses, by overlaying line-to-polygon, point-to-polygon, or polygon-to-polygon analysis. The analyses can be conducted using Euclidian distances or network-based distances. The buffering function allows spatial buffering analysis to be carried out using any variable of the analyst's interest. For modeling applications, the cross-referencing capability of GIS offers flexible choices between disaggregate travel modeling, for example, individual based trip generation and mode choice analyses, and aggregate, area-based operation such as gravity modeling of origin-destination interactions.

There are specialized software tools developed for specific data management, graphics, and statistical analysis functions. For example, dBase, MS Access, and Oracle Database specialize in data processing and management. AutoCAD and Rhino are popular computer-aided design and drafting tools. SAS, MATLAB, and Stata are long-standing powerful tools for statistical analysis. The value of GIS lies in its capability to integrate the three main functions of database management, graphics, and statistical analysis into one platform, although each of the three functions does not offer the full capacities that their respective specialized software tools do (Sharma, 2011).

GIS Enhancing Four-Step Modeling and Other Modeling Applications

GIS in/for Four-Step Transportation Modeling Procedures

Specialized GIS such as TransCAD, PTV, and Cube, target transportation planning and modeling applications. These packages make the prevailing transport modeling procedures, for example, the four-step models fully operable in a GIS environment. Data processing, especially spatial data, was not readily available in the past for transportation modeling. In the early stage of transportation modeling, when spatial data representation and processing was quite constrained, spatial data input was simplified. For example, land use characteristics were represented in a limited way by the density of population and employment at the TAZ level. Another value of GIS for model improvement is that GIS makes it less onerous to perform spatial statistics to address explicitly the issues such as spatial dependence and the modifiable area unit problems (MAUP) (Loidl et al., 2016).

The first step, trip generation, models the number of trips for the predefined geographic unit of analysis, typically TAZ, for the study region. This step reports two types of trip-making outcome: trips produced from and attracted to each TAZ.

For estimating trip generation rates, Metropolitan Planning Organizations (MPOs) often conduct activity-travel surveys that record and report the exact location and time information for each activity taken by the survey respondent during the survey day. The location information may come in as X-/Y-coordinates or street addresses. GIS enables identification and mapping of the activities through the built-in address-matching and other geo-coding procedures. By linking traveler activities with fine-grained urban form measures, GIS offers an effective tool to improve trip generation modeling greatly compared with the TAZ-based aggregate estimates (Clifton et al., 2015).

The second step, trip distribution, takes trip production–attraction tables as input and converts them into matrices of trip origin–destination (O-D). Most commonly, the step applies gravity-type models to distribute the trips estimated for each TAZ to other TAZs in the rest of the region according to the relative attractiveness of the TAZs and the travel time impedance among them. While the relational database structure employed by most GIS package enables integration of datasets from multiple, different data sources, the flat table-based data storage and retrieval makes it inefficient to handle matrix data commonly seen in transportation modeling applications. For example, a 1000 by 1000 O-D matrix would take one million rows in a flat table. Generic GIS packages in the market remain rather limited in providing matrix operation functions. Specialized GIS for transportation applications have developed quite sophisticated matrix handling capabilities.

The third step, mode split/mode choice, models shares or probabilities of various travel modes, that is, driving alone, carpool, transit, and walking or biking, for the trips estimated from step two. The output of this step contains O-D matrices of trips by different modes for different trip purposes. Modeling for mode split/mode choice may be carried out at the individual or household level or at the aggregate level such as TAZ. Hagen-Zanker and Jin (2013) introduce an adaptive zoning method to enhance the accuracy of mode choice modeling at the city or city-region scale. Rather than using a fixed boundary definition for TAZs, the method utilizes GIS to define interactively TAZs and generate TAZ data for modeling travel mode choice. The authors tested and showed that their GIS-enabled adaptive zoning approach retained information during rezoning and improved modeling accuracy by a factor of six to eight.

The last step, traffic assignment, of the four-step modeling process involves simulating the performance of transportation networks that are assigned with the trips of different modes and reports network conditions, mostly measured by level of service (LOS) as a function of traffic volume over capacity ratio, when all trips are loaded to the network. A variety of algorithms are available for the modeler to choose from for the task. Transportation networks consist of interconnected nodes and links that represent system components such as intersections and stops, highway lanes and transit lines. The network representation builds upon classic graph

theory. Vector GIS' topological data structure corresponds well with the graph theory-based network representation of transportation systems for model building.

For traffic assignment modeling, finding the shortest path (based on time, distance, cost, and other impedances) must take into consideration of turn impedances at network nodes and transfer impedances between routes. The model performance relies on efficient handling of spatial and statistical data across multiple spatial data layers. GIS presents unique capacities to strengthen and enhance the modeling performance compared with the purely statistical procedures (Shaw, 1993).

The four-step modeling procedures were originally developed without GIS. Many transportation professionals and consulting firms continue to use non-GIS computer packages for the four-step modeling. A converging trend is that these traditional transportation modeling packages evolve with enhanced visualization and spatial data processing capabilities while the generic GIS packages grow with more and more analytical modules for transportation applications (Slavin, 2004).

GIS for Accessibility Modeling

While the fundamental concern of transportation is the mobility of people and goods, the ultimate goal of transportation lies in providing access to services and opportunities essential to the economy and people's quality of life. Accessibility has thus been a central concept and indicator for assessing transportation system performance and for making investment and policy decisions. The evolving GIS capabilities contribute to accessibility modeling for a wide range of policy interest and applications (Liu and Zhu, 2004; Benenson et al., 2010; Lei and Church, 2010; Mavoa et al., 2012; Long, 2017). Conceptually, accessibility denotes to the ease to reach destination opportunities such as jobs, stores, schools, and health services. While social, economic, and political factors could become access barriers or facilitators, modeling accessibility typically considers two factors: destination attractiveness and transportation costs to reach the destination. Depending on modeling purposes, destination attractiveness can be measured by the number of jobs, the size of schools, stores, or medical facilities, etc. Measures of transportation costs for accessibility modeling may take a variety of forms (Miller, 2018).

A simplified accessibility model considers transportation system performance only, quantifying accessibility by access time or monetary cost without taking into consideration of variations in origin and destination attributes (Allen et al., 1993). The most widely used approach to model accessibility takes the form of gravity model (Hansen, 1959), incorporating the quantity and quality of destination opportunities. Discounting the attractiveness of the opportunities by the cost of reaching them, while the discounting function, also called friction function, varies in math expressions. Individual-based accessibility modeling quantifies a traveler's accessibility as the total utility associated with all travel means available to her/him. The value of accessibility can be derived from disaggregate choice models, that is, the logsum (Ben-Akiva and Lerman, 1985). Miller (1991, 1999) made a major breakthrough in accessibility research. He reconceives accessibility around Hägerstrand's (1970) space-time prism concept and operationalizes it in a GIS environment. Jarv et al. (2018) proposed and tested a conceptual framework of dynamic location-based accessibility modeling (Fig. 2).

Figure 2 Spatial-temporal modeling of accessibility. The maps (A) show differences in travel time to the closest grocery store at different times of the day. The graphs (B) show the population in the study area aggregated to given travel time difference categories. Source: Jarv et al. (2018).

While these various forms of accessibility models have been implementable computationally, GIS-based accessibility modeling tools have been developed to facilitate the application of them. Ford et al. (2015) also utilized OSM data, along with other data input from conventional sources, to develop an accessibility analysis tool. This tool takes advantages of many built-in features in ArcGIS and enables practically convenient and flexible operations to assess accessibility conditions by different transportation modes at current conditions and future infrastructure scenarios. O'Sullivan et al. (2000) developed a platform on desktop GIS for accessibility modeling. This tool uses input from shortest path in a transportation network to analyze patterns of spatial access (Fig. 2).

LUTI Models and GIS

Increasingly, state and local authorities are required to assess broad issues beyond vehicle movement to address the social and environmental dimensions of mobility challenges such as equity, emissions, air quality, and energy security. LUTI models are expected to offer analytical and modeling capacities to assist decision-makers for accountable assessments of mobility conditions and better-informed investment choices. LUTI models that sprang up initially in the 1960s have gained renewed interest recently, mainly due to the availability of spatial data and advances in computing technologies to process the data (Moeckel et al., 2018). These models offer sophisticated procedures not available in the existing commercial GIS packages such as ArcGIS, PTV, or TransCAD. Yet geographic information is essential to the new generations of LUTI models.

Traditional transportation modeling does not consider adequately the influence of land uses and other aspects of the built environment on travel outcome. Population and employment densities in most cases serve as the only representation of land use. Growth forecasts for future population and employment are done externally. In most cases, the modeling procedures consider no feedback of land-use changes (households' and firms' location and relocation moves) resulting from transportation improvements such as travel demand management (TDM), increased capacities of highway or transit, and applications of new technologies. Furthermore, traditional transport models operate largely with aggregate data at the TAZ level; they are rather insensitive to changes in local built-environmental conditions that have significant impacts on cycling and walking travel. LUTI modeling offers great potential to overcome the many limitations of traditional transportation modeling. Known examples of LUTI models include MEPLAN (Echenique et al., 1969; Echenique, 2004), MUSSA (Martinez, 1996), IRPUD (Wegener, 1996), PECAS (Hunt and Arabaham, 2003), and UrbanSIM (Waddell, 2002).

GIS Visualization for Transportation Modeling

The embedded cartographic functions in GIS enable effective and efficient visual presentation and communication of input data, intermediate analysis results, and the final output of various transportation modeling tasks. Traditional transportation modeling systems do offer graphing tools. Most of them, however, are limited to dot and line graphs. GIS offers way more options to visualize spatial and nonspatial data input and output. For example, thematic mapping allows the analyst to generate maps to visually present the attributes associated with transportation system components or performance conditions. For instance, the analyst may create dot-density maps to illustrate and compare the spatial distribution of population and jobs for the base year and the forecasting year. Desire-line maps can show O-D flows of passenger and goods movement, more intuitively informing than the original data stored in matrix files (Fig. 3). Traditionally, the analyst has used a letter scheme A~F to indicate highway LOS and congestion conditions. With GIS, LOS can be vividly presented using line-width maps based on the modeled volume-to-capacity (V/C) ratios.

Aside from 2-D mapping, GIS offers 3-D visualization functions. Kwan (2000) introduced several GIS-based methods to geovisualize in a 3D environment the spatial and temporal patterns of individual activities. She illustrates the application of these methods with travel diary data collected in the Portland, OR metropolitan region. Datasets obtained from activity-travel surveys record quite precise locations (e.g., X-/Y-coordinates) of activities performed by individuals in different time of day. GIS enables visualization of the disaggregate space-time data in a 2-D or 3-D environment (Kwan, 2000).

GIS-based transportation simulation is another area in which visualization plays an essential role. Transportation simulation refers to the imitation of people and vehicle movement in transportation systems under a virtual environment. There are many stand-alone transportation simulation software packages developed for academic research or professional applications. Examples of GIS-integrated tools include Cube Dynasim, PTV Vissim, and TransModeler, which are commercially available. These simulation tools model the behavior of transportation system and recreate travel reality in a two-dimensional or three-dimensional GIS environment. The range of transportation simulation applications vary widely. For example, one may simulate in a great detail and with high fidelity the performance of a street intersection involving through and turning vehicle traffic, bicycle and pedestrian flows, and their interactions with each other on the road space as well as their responses to traffic control devices such as traffic lights, stop and yield signs, and surface pavements.

These simulation tools may also apply to region-wide systems to simulate operational performance of proposed projects and plans. Examples of simulation applications include dynamic route choice behavior, public transportation uses as well as car and truck traffic under different traffic management policy schemes such as electronic toll collection, route, and traffic guidance under real-time traffic detection and surveillance. Traffic simulation results can also feedback to travel demand forecasting to improve transportation planning.

The power of GIS visualization goes beyond making beautiful maps. Visualization enables visual thinking to detect spatial patterns, generate hypotheses, and construct knowledge (Nollenburg, 2007). Visual thinking and communication involve cognitive

Figure 3 Visualization of transportation data in GIS: truck flow in Texas (*upper left*), super commute in Texas metros (*upper right*), and air passenger density in the United States. Source: Author.

processing of visual objects and information. Using GIS to display efficiently spatial data sets, the analyst can explore, understand, and convey spatial phenomena in ways that using words and statistics may find quite limited (**Fig. 3**).

Growing interest in geovisualization in the last 30 years have been driven by three forces (**Nollenburg, 2007**): (1) rapid advance in graphics and display technology owing to the availability of low-cost 3D graphics hardware and the development of highly immersive 3D virtual environments; (2) the dramatically increasing amount of geospatial data in a variety of forms, numbers, texts, images; and (3) the rise of the Internet-based medium for public engagement, which is important for both governmental agencies and business companies.

New GIS for New Mobility Modeling

Fast developing ICTs have facilitated the rise of shared economy and new mobility, which in turn propel the advance of GIS and transportation in their respective fields and present both challenges and opportunities for application of GIS to transportation modeling.

The first new challenge and opportunity is the growth of big data. Big data has emerged due to the widespread use of devices such as smartphones, GPS, transit smart cards, credit cards as well as the sensors, video cameras, and user-volunteered geographic information (VGI) available on the web via social media, Facebook, Twitter, and Instagram. These data have space–time information stored directly or inferable, offering the potential to broaden the scope and improve the quality of transportation modeling. Ziemke et al. (2017) demonstrate advantages of use VGI to overcome the data barriers to accessibility analysis and application by conventional accessibility models. This measure does not require population and land use (measures of opportunities at destinations) and network traffic performance data input as the conventional accessibility models do. Instead, the measure developed by Ziemke et al. (2017) relies exclusively on information extracted from OpenStreetMap (OSM). From a case study of Nelson Mandela Bay in South Africa, Ziemke et al. (2017) compare his approach with that using conventional approach and show comparable quality of insights into accessibility patterns but with operational and analytical advantages. Aside from lower input data requirements, the OSM-based accessibility measure offers the properties of higher interpretability, portability, and applicability to policy discussion and planning applications.

By definition, public transit (e.g., buses and subways) and taxi are traditional forms of shared mobility. New forms of shared mobility refer to a mobility service strategy that enables users to gain temporal access to transportation modes on an as-needed basis with no ownership of the transportation means (Shaheen and Chan, 2015). A variety of new forms of shared mobility services have emerged and grown, for instance, carsharing, stationed and dockless bicycle sharing and scooter services, ridesharing, ride-hailing, and transportation network companies (TNC) services, as well as future autonomous vehicles. Mobility-As-A-Service (MaaS) offers yet another mode of new mobility. MaaS is data-driven, powered by the growth of smartphone-based App development. MaaS integrates all modes of transportation such as carshare, bus, subway, taxi, and bikeshare and offers real-time optimized travel combinations as a single service package to the end users. Real-time geographic information, often crowdsourced, is key to the MaaS infrastructure (Goodall et al., 2017).

These new forms of mobility services rely on real-time, fast, and reliable information infrastructure. Real-time GIS offers information infrastructure support to the new forms of transportation and business services. Different from traditional GIS platforms that are static and stationed, real-time GIS offers information services capable of gathering, analyzing, and displaying streaming data from the Internet of Things (IoT) (Li et al. 2019). These data streams generated continuously by sensors, devices, and social media feeds are of high location and temporal granularity.

Conclusions

Transportation modeling has benefited from GIS greatly, while they evolve and advance in their own respective fields. GIS offers valuable contributions to transportation modeling mainly in three aspects. The first lies in the GIS platform that integrates the spatial and nonspatial input data from multiscale and multifunctional sources; quality and rich data input are essential to enhancing model performance. Second, GIS facilitates model calibration through refined spatial and temporal representation of transportation objects (e.g., people, vehicles, and infrastructure) and movements. In addition, GIS enables the modeler to consider explicitly the influence of spatial phenomena (e.g., spatial autocorrelation) on modeling results, which has been largely ignored in the traditional modeling work. Third, GIS offers powerful visualization capabilities for the modeler to communicate effectively the intermediate and final modeling output. GIS visualization is valuable not only in better informing the public and decision maker, but also empower the analyst to blend spatially oriented visual thinking with quantitative reasoning, gaining insights into complex travel behavior and transportation phenomenon.

The rapid growth of big-data industry and shared economy/shared mobility places new and increasing challenges and opportunities to transportation studies. GIS is also evolving from data processing as information tools to knowledge building as information science (GIScience) in an increasingly information-rich time (Goodchild, 2009; Onsrud and Kuhn, 2016). GIScience will continue to contribute to transportation modeling in a wide range of aspects, from basic data integration to dynamic, real-time optimization, and service delivering.

Definition

In economics literature, the term latent (or suppressed) demand is used to refer to the situation in which a consumer is unable to satisfy his/her needs due to nonexistence of the product or lack of awareness of the existence of the product and/or lack of affordability for purchasing the product. In the context of transport, latent demand specifically refers to the activities and travel that are desired but unrealized because of external constraints (Clifton and Moura, 2017). For example, non-car users may have a desire to visit a destination only accessible by car that constitutes the latent demand for that destination; the latent demand can be realized after instating public transport connectivity to the destination. Similarly, there can be a latent demand to purchase a car which is realized as the price of the car drops and/or the affordability of the consumer increases; there can be a latent demand to make more frequent social trips which is realized if there is a decrease in the congestion level; there may be a latent demand for increased mobility among the elderly and/or disabled population which can be realized when the self-driving cars become widely available (Wadud et al., 2016).

A closely related term in economics is induced demand which is the increase in demand observed as a result of the increase in supply and the associated reduction in generalized cost^a. In the context of travel, investments in transport typically lead to improvements in the levels-of-service in the short term which encourages people to travel more. This can occur through a variety of behavioral mechanisms including mode shifts, route shifts, redistribution of trips, generation of new trips, and long-run land-use changes that create new trips and/or longer trips (Noland, 2001). The “new” travel spurring from new or improved transport infrastructure and operational measures is known as induced travel. It may be noted that, in the network level, the “new” travel should only include the travel above and beyond those made originally to avoid overestimation.

Although the transportation literature uses the terms latent and induced demand somewhat interchangeably, in strict definitions, latent demand represents currently desired demand that is not realized because of a wide variety of constraints (including nonexistence of a mode or technology, lack of purchasing power, etc.) while induced travel would not occur without transportation system improvements and is stimulated specifically by the capacity enhancements.

The graphical representation of induced travel after a transport investment leading to enhancement of capacity (i.e., supply) is shown in Fig. 1. In Fig. 1A, it is assumed that the population and demographic effects (such as employment rates), which can also lead to an increase in demand levels, are held constant. The line S_1 represents the original supply, and C_1 and Q_1 are the corresponding costs and quantity of travel (e.g., vehicle miles traveled (VMT)), respectively. Capacity expansion (or another form of transport investment) lowers the cost of travel to C_2 and the supply is shifted downward (S_2) (since the same demand is met at a lower cost) leading to an increase in travel (Q_2). The increase in the quantity of travel from Q_1 to Q_2 represents the induced travel effect.

In Fig. 1B, the changes in population and/or economy are also accounted for. The demand curve is assumed to shift outward from D_1 to D_2 (e.g., due to population and/or economic growth in the area). Simultaneous to this, the supply curve shifts down. As a result, the quantity of travel (Q_3) increases even more than in Fig. 1A. In this case, the increase in quantity due to exogenous growth is the difference between Q_3 and Q_2 and the induced travel is the difference between Q_2 and Q_1 .

^a In transport economics, the generalized cost is the sum of the monetary and nonmonetary costs (e.g., travel time) associated with travel translated to monetary unit.

Figure 1 Graphical representation of induced travel. (A) With no population and/or economic growth, (B) accounting for population and/or economic growth.

Implications

In the short run, when residential and employment locations are fixed, improvements in transport infrastructure and/or operational measures can lead to changes in travel departure times and/or destinations, route switches, mode switches, and/or additional trips. Among these, changes in mode and increase in trip numbers have a direct contribution to induced travel. Change in departure time (usually a shift from off-peak to peak) can free up capacity at other times of the day leading to new trips being made at those times and have an indirect contribution to induced travel. On the other hand, choosing a different destination and/or route can result in either shorter or longer distances being traveled. If the net effect of these changes is increased travel, it also contributes to induced travel (Noland, 2001).

Further, in the long run, faster speeds encourage additional social and economic activities in areas made more accessible by the new highway capacity. This can lead to changes in land use, residential and employment locations, and in many cases, an increase in trip lengths in the long run.

The theoretical benefits due to the transport investment are hence offset and often completely diminished due to the latent demand and induced travel. The finding has even been dubbed the “Fundamental Law of Road Congestion,” which asserts that the elasticity of VMT with respect to lane mileage is equal to one, implying that driving increases in exact proportion to highway capacity additions (Downs, 1962). It may be noted though that if the traffic is diverted from other routes, it is expected to lead to a decrease in congestion elsewhere and in network-level analyses; this should be factored in to avoid overestimation.

In terms of wider benefits, given transport is a derived demand, meeting latent demand can contribute to improving the quality of life of the travelers by offering increased mobility and better access to employment and other opportunities. These net benefits of the travelers from transport investments can be measured by measuring the changes in consumer surplus^b (the shaded triangle in Fig. 1).

Methods for Predicting Induced Travel

The latent demand and induced travel can be predicted by econometric and transport model-based approaches. Further, historical evidence based on before–after analyses is also used to approximate latent demand in similar projects.

Econometric Method

In the econometrics studies, the relationship between induced travel (measured by VMT) and road capacity (generally measured by an increase in lane-miles) is established, typically using regression approach (Department of Transport, 2018):

$$\text{Log}(\text{VMT}_{it}) = a_i + \beta_t + \gamma \text{Log}(\text{lane-mile}_{it}) + \sum_k \delta_k X_{kit} + \varepsilon_{it} \quad (1)$$

^b Consumer surplus is the difference between the price that consumers pay and the price that they are willing to pay. On a supply and demand curve, it is the area between the equilibrium price and the demand curve.

where subscripts i and t refer to area and time period, X represents a set of k control variables. Using logarithmic forms of the dependent VMT and lane-mile variables means that the coefficient γ can be interpreted as the elasticity of VMT with respect to lane-mile, the proportionate response in demand to an increase in road capacity^c.

However, transportation planners, for example, do not randomly select which highways to widen. Instead, they prioritize improving highway segments with unacceptable levels of traffic congestion or in areas expecting economic growth. Therefore, though travel is highly correlated with capacity, it is not plausible to assume that causality flows in a single direction. Rather, highway capacity itself is endogenously^d determined by the volume of vehicle travel and other factors (Hymel, 2019). Failing to control for endogeneity in a travel demand model will likely generate biased estimates of the induced demand elasticity. Instrumental variables (IVs) are used to avoid endogeneity bias in predicting VMT. Commonly used IVs include lagged values of highway capacity growth (Fulton et al., 2000), the amount of urban land area (Noland and Cowart, 2000), and a combination of political and environmental measures (Cervero and Hansen, 2002).

Transport Model-Based Analyses

In transport model-based analysis, models to simulate land use and/or travel demand behavior, calibrated with existing data, are used to predict the travel behavior in post-investment scenarios. The induced travel is reported as percentage changes in traffic relative to the baseline in most cases rather than the change in vehicle-miles (though the latter can be calculated from most models as well). This makes the model-based studies difficult to compare with the elasticities reported in econometric studies. It may be noted though the background traffic growth and reassigned traffic need to be controlled for to get meaningful estimates from the model outputs. Further, the models typically involve some assumptions and there are often concerns associated with the spatial and temporal transferability of model parameters. These make it challenging to generalize the values derived from modeling studies.

Case Study-Based Analyses

Similar to the modeling studies, in the case studies approach, the induced travel associated with a specific road network improvement is reported as a percentage change in traffic relative to the baseline (i.e., change in vehicle numbers) since quantifying changes in VMT is extremely challenging in the real world. Due to potential confounding with other factors affecting demand, the case studies-based approach also needs to be carefully controlled for other associated changes and traffic reassignment. The challenges associated with the transferability of the values also persist.

Empirical Findings

The extent of latent demand and induced travel tends to vary considerably with the location and type of transport improvement and depends on the time horizon, unit of measurement, and method deployed. Some indicative values are presented later, though, due to the issues associated with transferability, the values should be considered with caution:

- The “Fundamental Law of Road Congestion” puts forward the proposition that the highway capacity expansion generates an exactly proportional increase in vehicle travel ($\gamma = 1$). Most of the empirical studies report this as the upper limit, particularly after controlling for the background growth and factoring in the reassignment.
- The short- and long-run elasticities tend to vary significantly. For instance, in the context of US highways, the short- and long-run elasticities are reported to be in the range 0.46–0.59 and 0.9, respectively (Fulton et al., 2000).
- Modeling studies reporting at the city region scale find smaller percentage changes in traffic flows due to induced traffic (0.7%–3.84%), compared with 5% on the main road link (Department of Transport, 2018).
- The highest increases in traffic volumes were found to occur for schemes where the baseline traffic volume was high or the route is close to capacity. Assuming that the percentage change in volume relative to the percentage change in capacity provides a rough elasticity estimate, the data from this study indicates elasticities of 0.5–1 for the congested and high volume routes but much smaller elasticities for other schemes (Davies, 2015; with data based on seven schemes in Australia).
- The relative contribution of absolute increase compared to increase due to changes in mode, destination, and route are typically difficult to identify. However, in the context of a major motorway improvement scheme (Manchester Motorway Box), a 15%–17% increase in car trips was observed of which the majority were attributed to changes in the destination (9%) and less to mode shift (4%). The demographic and employment effects were explicitly accounted for using detailed land-use data for the area and accounted for between 2.5% and 3% of the changes (Rohr et al., 2012).

^c Differentiating (1) $\gamma = \frac{\text{lane-mile}}{\text{VMT}} \cdot \frac{\partial \text{VMT}}{\partial (\text{lane-mile})}$.

^d Endogeneity refers to situations in which an explanatory variable is correlated with the error term.

Outstanding Issues

The importance of accounting for latent demand and induced travel is widely acknowledged. However, the challenge in incorporating it in transport cost–benefit analyses or other planning decisions lies in accurately predicting the amount of induced travel. Given the values being highly location dependent, it is not straightforward to simply “borrow” values from other similar studies. The lack of suitable data often makes it impossible to calculate it in a rigorous manner. Further, there are challenges associated with controlling for the background growth and the potential traffic reassignments. Moreover, induced travel very often occurs due to land use and/or economic growth stimulated by the transport project; this land-use change benefits and/or costs also need to be captured in the calculations which are a nontrivial task. The lack of evidence of latent demand and guidance for calculating it is more acute in case of public transport where it is often more challenging to measure the VMT equivalent.

Another well-acknowledged, yet under-researched area is the calculation of the cross-modal interactions that lead to induced demand. For example, a new high-speed rail connection between two cities may lead to increased economic activities between them leading to an increase in car trips. This also remains an area of ongoing development.

Information and Communication Technology

Information and communication technology (ICT)—also used in the plural form, that is, information and communication technologies, or ICTs—has a central role in a growing number of contexts related to activity decisions and travel choices. The concept has entered the broader scientific discourse in the 1980s reflecting the convergence and ever-tighter coupling between computing (information processing) and telecommunications that started in the late 1970s and early 1980s. The subsequent decades saw the mass adoption of personal computing- and telecommunications-capable devices (hardware), with a big expansion in the access to the internet and, more recently, the adoption of mobile devices, together with all their capabilities and services (software). All of those have placed ICT among the key factors shaping societies, hence also warranting the analysis of their important role in the contexts of activity decisions and travel choices.

Despite its popularity, the term ICT has lacked a single, authoritative definition. For instance, the Dictionary of Media and Communication ([Chandler and Munday, 2012](#), p. 120) defines the meaning of ICT in a rather broad sense:

“An umbrella term for all of the various media employed in communicating information: for example, in an educational context ICT may include computers, the internet, television broadcasts, and even printed or handwritten notes.”

While flexible, such a general interpretation is very broad and not very conducive to the analysis of the role of ICT in relation to activity decisions and travel choices. The International Telecommunication Union (ITU), a specialized agency of the United Nations responsible for issues that concern ICT, groups the indicators describing the state of ICT into four main technological families ([ITU, 2011](#)):

- fixed-telephone networks;
- mobile-cellular networks;
- the internet;
- broadcasting.

Within each group, the indicators are defined so that they are measurable (quantifiable) and thus allow the comparison of the state of ICT sectors in various regions and countries. The ITU approach is strongly hardware- and communications-centric, though. This may be limiting when it comes to acknowledging changes occurring in the “softer” layer of ICT, that is, capabilities, services and applications. From that standpoint, the most appealing definition has been offered by the [OECD \(2004, p. 3\)](#), which has also been employed by the [ITU \(2011, p. 133\)](#), to describe ICT goods and services as those:

“ . . . intended to fulfil the function of information processing and communication by electronic means, including transmission and display, or use electronic processing to detect, measure and/or record physical phenomena, or to control a physical process.”

Such definition is focused on the functionalities and capabilities offered by ICT while explicitly acknowledging the role of electronic means, thus excluding various non-electronic (“pen and napkin”) information processing and communication possibilities. The definition is also particularly attractive in its emphasis on the role of ICT as a means of interacting with the reality, thus enabling new forms of activity participation, themselves of crucial importance in the context of activity decisions and travel choices.

In that sense, ICT solutions more concretely include:

- fixed and mobile (cellular) telephones, including smartphones;
- computers, including desktop, portable (laptops, tablet), high-performance computers, and servers of various kinds;
- any other stationary or portable devices capable of information processing or communication, including portable digital assistants (PDA), TV and radio sets, music players, game consoles, wearable technologies, home appliances;
- the internet, including technologies enabling its operation, that is, data routing, and accessing, for example, WiFi, fixed broadband, mobile broadband (including 3G, 4G, and 5G standards);
- other networks, for example, local area networks (LAN), intranet, adhoc networks;
- various sensing technologies with information processing and communication capabilities, including closed-circuit television, satellite-based sensing, automatic traffic counters;
- software utilized by the aforementioned hardware, both based directly on the local devices and on remote servers (the cloud), to enable the services, applications, and communication through information processing and transmission.

The list above is not exhaustive, but acts as a convenient “entry point” to understanding what ICT means in the context of activity decisions and travel choice analysis. Any specific analysis of ICT requires establishing a working definition tailored to the context, including consideration of the scope of technologies interpreted as ICT, the level of detail in their specification, time horizon, or the range of applications and capabilities considered.

In the past three decades, the transportation research community has shown a strong interest in understanding the impacts of ICT adoption on activity participation and travel choices. This interest has been motivated by early hopes of mitigating travel demand and reducing congestion through substitution with an ICT-based means of activity participation. Despite the ICT-travel substitution having been often below expectations, the topic regularly regains prominence in the transportation planning research agenda during periods of large-scale and prolonged disruptions to transportation systems. Such disruptions can be man-made, for example, large-scale events in densely populated areas, for example, London 2012 Olympics, or nature-made, such as air travel disruptions following the 2010 Eyjafjallajökull volcano in Iceland. However, not until the COVID-19 pandemic in the first half of 2020 has the potential of ICT been shown vividly at a scale. With lockdown measures that limited physical travel within and between countries, large portions of populations were forced to operate from their homes. Where possible, individuals started to rely on ICT tools for work activities and social interactions, causing the adoption rate and frequency of many ICT-enabled activities to soar. It remains to be seen to what extent these unprecedented circumstances might translate into long-lasting changes in the relationships among ICT use, activity participation, and travel choices (and eventually requiring revisiting the existing evidence and knowledge).

Related Concepts in the Analysis of Activity Decisions and Travel Choices

A number of concepts in the field of the analysis of activity decisions and travel choices are often seen alongside ICT in a variety of modeling, policy, and planning contexts, including:

- tele-, online, digital, and e-activities;
- smart and mobile capabilities;
- digital divide and digital skills;
- intelligent transport systems (ITS);
- big data.

Unfortunately, a detailed understanding of their respective interactions with ICT is often hampered by the lack of clarity on the terms’ meaning and often adhoc and lax interchange of the terms in use. To facilitate clarity, below we provide working definitions to distinguish the concepts and more directly relate them to the context of ICT, activity decisions, and travel choices.

Tele-, Online, Virtual, Digital, and e-activities

In the broadest sense, *teleactivities* (or tele-activities) refer to activities conducted remotely (from the Greek word *tēle* meaning “far off”). The concept has remained in use since at least 1970s, when the phrases of *teleworking* and *telecommuting* were coined and popularized in the wake of the energy crisis of 1970s (Bailey and Kurland, 2002; Mokhtarian, 2009). A comprehensive review from a decade ago (Andreev et al., 2010) highlighted the existence of (already then) substantial research concerning teleactivities and their interactions with travel behavior, including teleworking and telecommuting, teleconferencing, teleshopping, teleservices, teleleisure.

Notably, teleactivities are focused on participation in an activity that is spatially separated from the location in which the activity would traditionally take place. This original meaning implicitly embodies ICT-facilitated participation. The concept does not specify, however, either the need for existence of communication between the locations. For instance, word processing or writing a piece of a computer program can be standalone teleactivities. If/when such communication occurs via a modern telecommunication means, typically the internet, the activity becomes an *online activity*.

On the other hand, participation in a *virtual activity* invokes the notion of virtual reality. Steuer (1992, p.6) offers a convenient conceptual link with teleactivities through the notion of *telepresence* defined as “the experience of presence in an environment by

Figure 1 Hågerstrand's representation of a telephone call in the context of activity decisions and spatiotemporal constraints. *Source:* Created by the authors, based on Figure 2 in Hågerstrand (1970)

Table 1 ICT-related activity concepts

Activity concept	Focus implied by the definition	The relationship to ICT
Teleactivity	Spatial separation between the activity participant and location of the activity in its traditional version.	ICT as an enabler of the remote activity participation.
Online activity	Use of a telecommunication medium.	ICT as modern telecommunication technologies, enabling exchange of information for activity participation.
Virtual activity	Relying on the ability to create a sensory-rich experience of presence in an environment (virtual reality).	ICT as a means of creating sensory rich experience, including communication.
Digital activity	Relying on technologies for digital processing and communication of the information.	ICT as technologies using digital processing of information to enable activity participation.
E-activity	Use of electronic technologies.	ICT as technologies that are electronic and enable activity participation.

Source: Created by the authors

means of a communication medium." Following from there, a virtual activity can be defined as one conducted in virtual reality, that is, "a real or simulated environment in which a perceiver experiences telepresence" (Steuer, 1992, p.9).

The reference to the use of a particular technology, hardware or software, that processes information digitally (i.e., as binary digits) is a defining feature of a *digital* activity. Similarly, the use of *electronic* technology, whether for computing or communications, to conduct an activity defines the term *e-activity*. As nowadays ICT are almost exclusively digital and electronic, this helps explaining an almost synonymous use of the terms in modern contexts. A summary of the above concepts is presented in Table 1.

In the analysis of the activity decisions and travel choices, early research hypotheses (and hopes from policy makers) assumed the emergence of teleactivities to be a panacea for transportation (road, in particular) congestion, enabling substantial reduction in the demand for travel. This reduction was supposed to be fueled by the expanding range and sophistication of the activities facilitated by ICT, including those enabling online and virtual reality experience. Nowadays, this interpretation is known to be incomplete, with interactions being much more elaborate. Section 3 of this chapter discusses the conceptual and modeling frameworks and taxonomies that have been proposed to analyze such interactions.

Smart and Mobile Capabilities

The notion of *smartness* is increasingly prevalent in the mobility discourse, that is, concerning activity decisions and travel choices. Smart ICT devices are those that are capable of processing information and of communicating with other devices with a substantial degree of autonomy, while also providing a considerable means of interaction with the user. In the mobility discourse, the notion of a smart ICT device is nowadays almost always accompanied by the notion of *mobile devices*. A mobile device is designed to allow the realization of its information processing and communication capabilities without the continuous reliance on fixed infrastructure, for example wired connection or power supply, and with the device dimensions facilitating portability.

The mass adoption of smart mobile ICT devices such as smartphones, portable computers, and wearable technologies, has been a major driver behind the emergence of new business models and technological solutions in mobility. Those range from advanced and real-time trip planning and navigation, to service offering comparison, frictionless payment and ticketing, shared mobility, and/or on-demand mobility services.

Digital Divide and Digital Skills

The adoption and use of ICT require access to resources (devices, infrastructure) as well as the acquisition of the appropriate level of skills. The uneven access to or ability to use ICT among groups defined on social or geographical grounds is referred to as *digital divide* (OECD, 2006). The term can be observed in absolute terms, for example, access to ICT or lack of it, as well as in relative terms, for example, varying quality of connectivity. The term in the mobility context has particular relevance as it highlights variations in people's ability to benefit from advances in ICT in the context of mobility.

The accompanying concept is that of *digital skills* which refers to individual capabilities and knowledge concerning the use of ICT. ITU (2018) defines a number of such skills along which they measure the ability to use ICT:

- copying or moving a file or folder
- sending e-mails with attached files
- using copy and paste tools
- transferring files between a computer and other devices
- finding, downloading, installing, and configuring software
- connecting and installing new devices
- using basic arithmetic formulas in a spreadsheet
- creating electronic presentations
- writing a computer program

While regrettably often overlooked in travel-behavior analysis, the concept is key to comprehensively understand any postulated impacts from ICT on activity decisions and travel choices. Using a parallel to car access and driving license possession, the potential neglect of the digital divide and digital skills in the analysis of ICT in the context of activity decisions and travel choices would be the counterpart of assuming a universal access to a car and driving license possession. While the assumption holds in some contexts, in others, such as for certain segments of the populations (e.g., elderly, rural dwellers, etc.), it clearly does not, possibly resulting in ineffective or unequitable policies.

Intelligent Transport Systems (ITS)

Even if they are not the main object of discussion of this chapter (but are discussed in other chapters of this book), intelligent transport systems (ITS) warrant a brief mention in the present context due to their close relation to the concept of ICT, and hence a potential conceptual confusion. In probably the simplest terms, ITS applications make use of ICT to deliver advanced transportation systems operation and management capabilities. Thus, ITS are focused primarily on providing efficient *transportation supply*, toward which end they make use of ICT to process the relevant data and allow communication and coordination between transportation systems' components (hence ITS are increasingly referred to as Cooperative ITS, or C-ITS).

The use of ICT for activity decisions and travel choices does not need to involve ITS. An example is a decision to make use of ICT to enable an online activity participation and not travel, which affects *transportation demand*. Still, the deployment of various types of ICT-based ITS solutions have important implications also in terms of their effects on activity participation and travel choices.

Big Data

Big data conventionally refers to the notion of analysis of very large datasets using modern, large-scale computation capabilities for the purposes of obtaining insights that could not have been obtained using a more traditional analytical means. Big data are typically characterized by so-called 3Vs: large *volume*, substantial *variety*, and high *velocity*. The role of ICT in the space of big data is two-fold: it enables big data analysis itself as well as the creation of big data in the forms of *digital footprints* and *data fumes*. The former function of ICT has a very direct role in the field of activity decisions and travel choices, enabling new methods of inquiry.

The role of ICT as enabler of digital footprints and data fumes requires further elaboration. *Digital footprints* are traceable data points created by individuals as the result of their participation in digital activities. Such footprints can take the form of content generated by a person online, including textual or visual, or their choices, including website selection or goods and services purchase. Datasets generated in this manner can be collected and analyzed to better understand people's activity decisions and travel choices, in light of the growing role of digital activities in people's lifestyles.

A related concept is that of *data fumes* which also refers to user-generated data, but more often passively collected and often without user awareness. The records of online activities as well as those generated by the devices on the network, such as traces, transactions or incidents, can also be harvested for the purposes of mobility analysis.

Following experimental approaches in the 2000s, big data applications have now made it to the mainstream analysis of activity decisions and travel choices. The broad opportunities allowed by the analysis of big data in transportation planning are not the main focus of this chapter, but are discussed in details in other chapters.

Frameworks for Analyzing ICT Interactions With Activity Decisions and Travel Choices

Arguably what can be seen as the earliest reference to how ICT may be interacting with activity decisions and travel choices was made in Torsten Hägerstrand's presidential address (1970) in which he stated:

"Telecommunication allows people to form bundles [joining other individuals in a common activity] without (or nearly without) loss of time in transportation." (Hägerstrand, 1970, p.15)

More broadly, Hägerstrand's theory developed the idea of *space time paths* along which individuals move (see Figure 1). By embodying the idea of a telephone, which escapes what are otherwise the spatiotemporal constraints on individuals having to travel to conduct an activity, he proposed what was effectively the first link among the predecessor of modern ICT, activity decisions and travel choices. Remarkably, the conceptualization is still largely applicable to modern teleactivities.

In the 50 years since then, many research studies have discussed how ICT can affect many aspects of human life, ranging from long-term choices, for example, relocation and migrations, to medium-term choices, for example, vehicle ownership, to short term-choices, such as the organization of activities, including those performed for work/business and/or leisure/social purposes, and trip-related choices, including destination, travel mode, departure time, and route choices. All these impacts of ICT can have plenty of direct or indirect effects, sometimes in conflicting directions, on various components of travel demand (Circella and Mokhtarian, 2017).

According to the taxonomy introduced by Salomon and Mokhtarian in the late 1980s and 1990s (Mokhtarian, 1990; Salomon, 1986), one which has remained remarkably stable over the years, interactions between ICT and travel behavior can occur at different levels. *Substitution* takes place when an individual chooses to conduct activity by means of ICT, that is, as a teleactivity, rather than in physical reality, thus reducing or even eliminating the need to travel. In its pure conceptual form, substitution should result from an individual still undertaking an activity, but in its ICT-based form instead of traveling to a location where the physical activity would have been undertaken. In practice, however, research studies frequently identify net substitution as measured by a reduction in the amount of travel.

An opposite effect to that of substitution is *complementarity* (sometimes referred to as *generation*), in which case the use of ICT leads to an increased amount of travel. Such situation is supposed to result from ICT-induced easier access to information and cheaper communication leading to increased awareness of various opportunities, also at more distant locations. Moreover, cheaper communication could provide a means for maintaining larger social networks, potentially translating into additional demand for physical meetings, and thus travel. Such effects could emerge at different scales, ranging from local leisure-related meetings to global professional networks and potential expansion into new markets, with the consequent need for international business travel.

The substitution and complementarity constitute extreme cases of interactions between ICT and travel behavior, focusing on the sheer amount of travel. In situations when travel still takes place, at least partly, ICT can lead to *modifying* activity-travel patterns in terms of, for instance:

- trip purpose(s) and/or destination(s);
- trip timing;
- route;
- mode(s) of travel;
- use of travel time (travel-based multitasking).

The final effect of *neutrality* is a limiting case of the other three types either not existing or canceling each other, and thus resulting in *net* neutrality.

In addition to the earlier, there are also higher order interactions that involve ICT influencing other aspects of individual lifestyles and long-term choices (residential choice, mobility and time use preferences, and vehicle ownership) or even society and economy (social norms, urban form, smart infrastructure provision, and market organization). Such impacts can subsequently propagate to ultimately affect activity-travel patterns. At the same time, such higher order interactions take place over longer time due to various rigidities and inertia in socioeconomic systems, including durations of rental contracts, investment time spans, regulations' design, introduction, and implementation, as well as habits, customs, and lack of trust in novel technologies among others. It should be noted, however, that the two different levels of interaction are artificial constructs to systematize understanding. In reality, interactions at different levels would be closely interconnected, for example, long-term substitution of activity could only occur if its tele-counterpart is trusted.

It should be also noted that ICTs as a travel replacement strategy have been seen for many years as a solution to many societal problems, including urban congestion, dependence on non-renewable energy sources, air pollution, and greenhouse gas emissions. The role of ICT in overcoming physical remoteness has been suggested as a way to overcome physical boundaries and limitations such as rural underdevelopment, reduced economic opportunity for the mobility-limited, and the struggle to balance job and family responsibilities of many segments of society (Mokhtarian et al., 2005; Salomon and Mokhtarian, 1998). The evidence in the literature has shown that use of ICT certainly can replace "a lot" of travel, but at the same time can generate additional and modify other travel. It contributes to relaxing some physical boundaries and constraints, while also imposing new ones, such as the dependence on the availability of appropriate hardware and software (and charging facilities and batteries), and access to reliable communication networks.

In addition to the above classical view on of ICT in the context of activity decisions and travel choices, ICT has also been discussed as offering increased opportunities for the adoption of *multitasking* behaviors, increasing the ability to overlay multiple activities performed “at the same time” but also causing *activity fragmentation*. These time allocation phenomena have been hypothesized as being enhanced by the proliferation of ICT. In the case of multitasking, Kenyon and Lyons provided a concise definition of the concept (Kenyon and Lyons, 2007, p. 162):

“[multitasking is] simultaneous conduct of two or more activities during a given time period.”

The importance of the multitasking phenomenon lies in its potential of relaxing the conventional microeconomic time allocation theory assumption that the total duration of activities an individual can conduct during a specified period is fixed. This assumption underlies most of the modern transport investment appraisal methodologies and its relaxation may have implications for methods for travel time valuation. The incorporation of multitasking in the analysis of activity choices and travel decisions, and particularly in the context of so-called travel-based multitasking, has become of particular importance recently, fueled by the proliferation of mobile ICTs as well as by the expectations regarding new transportation technologies, and in particular connected and automated vehicles. Circella et al. (2012) provides a comprehensive theoretical discussion on multitasking and related concepts, while the framework of Pawlak et al. (2015) demonstrates how ICT, teleactivities, and multitasking are interrelated in the context of activity decisions and travel choices. Lastly, Keseru and Macharis (2018) and Pawlak (2020) have provided systematic reviews of empirical studies, also in reference to ICT use in the context of travel-based multitasking.

The phenomenon of *fragmentation* describes the relaxation of the traditional boundaries defining spaces and times characteristic to certain activities (Couclelis, 2009, p. 1560):

“Instead of occupying compact chunks inside the daily prism, ICT-aided activities tend to disintegrate into sets of discrete tasks which get spread out across places and over time.”

In other words, fragmentation refers to conditions in which conventional hours and locations typical for activities, for example, work between 9 am and 6 pm in an office, become increasingly invalid as a result of ICT-enabled flexibility in the form of teleactivities.

Outlook for the Future

During recent decades, the society has experienced a sharp growth in the adoption of ICT. Initially constrained to only a handful of industrialized countries, ICT-based solutions have become widespread also in developing countries and emerging economies, thanks to the adoption of mobile communication and smartphone technologies that helped overcome the eventual lack of physical infrastructure. ICT has generated a variety of new products and services—including new shared mobility and on-demand mobility services - and novel solutions for business-to-business and business-to-consumer transactions, the dematerialization of the goods, fast communication and social connections at distance, with complex implications on the resulting activity patterns and travel demand, as discussed by Pawlak et al. (2020). Moving forward, transportation researchers question to what extent past trends and established knowledge based on the former will hold for the future.

Certain ICT applications, such as e-commerce, have already altered the modern life as well as the physical shape of cities and regions significantly. For example, the growing internet penetration and the consequent stimulation of e-commerce altered individuals' shopping behaviors and spending patterns. It has also significantly grown into the retail sector and generated structural changes to supply chains and the organization of retail space itself, through the disappearance of many stores themselves, and the emergence of combinations of “bricks-and-clicks” forms of retail that include both physical presence with traditional stores complemented by online e-shopping.

In the year of publication of this chapter, the COVID-19 pandemic has caused large portions of the world population to abruptly reduce their amount of travel and their participation in in-person activities. During the pandemic, ICTs have been used as substitutes for travel for many activities at much higher rates, and across larger segments of the population, than in the past, causing significant reductions in vehicle miles traveled (VMT) for all trip purposes but also a large drop in the use of public transportation or shared mobility, i.e. the travel modes that might be more conducive to the transmission of the disease. This could create a substantial challenge for transportation demand management, making private car a particularly attractive alternative, as activities gradually reopen but travelers remain hesitant about using “shared” modes of travel. It remains to be seen, though, whether the extended time over which individuals have been forced to modify their habits and embrace ICT-based alternatives might have caused changes in the way that ICT interact with activity decisions and travel choices, with consequently long-lasting impacts on individuals' behaviors and lifestyles.

Why Model Transit Ridership?

Ridership is a key measure of a transit system's performance. It is a direct indicator of the extent of use of a transit system and an important determinant of the revenue generated. Understanding and modeling transit ridership is useful primarily for two purposes:

1. To forecast transit ridership for evaluating long-term urban planning strategies, such as transportation project investments (e.g., introduction of a new transit service for the city) and land-use strategies (e.g., transit-oriented developments). Such long-term forecasts help in assessing project feasibility, evaluating alternative plans and scenarios, and estimating environmental and social impacts of transportation projects.
2. To provide objective means of assessing ridership and revenue changes following improvements by the transit agencies. Public transit agencies continuously endeavor to improve their services through a variety of strategic and operational improvements. Such improvements include addition of new routes, increases in service frequency, changes in schedules and service network, and pricing. These also include connectivity to and from other modes of travel, such as feeder services to metro stations, improvements in amenities at stations and stops, designation of transit priority corridors, and provision of information to travelers. These improvements are aimed at increasing service efficiency, ridership, and revenue, and enhancing the service coverage. Ridership forecasting models can be used by transit agencies to assess the possible impacts of the improvements on ridership and revenue.

This chapter begins with an overview of the different approaches to modeling transit ridership. It then delves into direct demand models that are used to model aggregate ridership as a function of the factors influencing it. The challenges in developing and applying transit ridership forecasting models are discussed in the section on model design considerations. Following that is a discussion on the model structures and explanatory variables used in ridership prediction models. The chapter concludes with a discussion of emerging trends that impact transit ridership analysis and future directions.

The focus of this chapter is on fixed-route, fixed schedule bus transit systems. However, many of the considerations also apply to rail transit and to bus transit systems with flexible routes and schedules.

Approaches to Modeling Transit Ridership

Modeling transit ridership for a study region involves estimating the number and demographic distribution of riders who use different transit services. It also involves estimating the spatial, temporal, and route distribution of ridership as a function of the socio-demographic, land-use, and transportation service characteristics of the study region, including the service characteristics of the transit system. Most approaches to modeling transit demand may be classified into two broad categories: (1) City-scale or regional travel demand model systems, and (2) Direct demand models. Each of these is briefly discussed further, with direct demand models being the focus of the rest of the chapter.

1. City-scale or regional travel demand model systems are aimed at predicting a region's aggregate travel patterns as a result of the trip makers' choices of whether to travel and how much, as well as why, when, where, and how to travel. These models can be structured in two broad forms:
 - a. aggregate, trip-based travel demand models
 - b. disaggregate activity-based travel microsimulation models

The aggregate, trip-based travel demand models often involve the four-step approach used to estimate (i) trip generation or total trips generated for each spatial zone in the study area; (ii) spatial distribution of the trips between each pair of zones; (iii) modal split of trips, including transit ridership between each pair of zones; and (iv) assignment of traffic to highway and transit networks. The disaggregate, activity-based models focus on microsimulating the travel choices of each individual in the study area toward estimating aggregate travel patterns. Using such disaggregate models, one can estimate the aggregate spatial, temporal, route, and demographic distribution of transit ridership (Pinjari and Bhat, 2011). Mode choice models form the basis for estimating transit ridership in these models.

2. Direct demand models, as the name suggests, are aimed at directly modeling aggregate transit ridership, typically in the form of statistical regression models that relate ridership in an area over a specific time period to the various factors influencing it. It is worth noting here that, even if there were access to a regional travel demand model system, transit agencies that operate large transit systems would benefit from developing their own ridership forecasting models in the form of direct demand models. This is because direct demand models can be used to answer questions of interest to transit agencies that many regional travel demand models in use might not be helpful for. For example, regional travel demand models might not include enough detail to forecast ridership impacts of changes in transit stop-level amenities and accessibility. Even if they do, it might be easier to run a simpler direct demand model than to run a large-scale regional travel demand model. Further, direct demand models can be structured to utilize information from regional travel demand models. Once developed, these models are quick response in nature and less expensive in terms of time, cost, and data requirements when compared to large-scale travel demand models. A large body of literature exists in this area (Peng et al., 1997; Chu, 2004; Chu, 2007; Polzin et al., 2011; Gutiérrez et al., 2011; and Chakour and Eluru, 2016). Most of the literature, however, is based on developed economies and not much exists in the context of developing countries.

Direct Demand Models for Forecasting Transit Ridership

Ortuzar and Willumsen (2011) describe a direct demand model as one that subsumes trip generation, distribution, and mode choice. They cite the SARC (Kraft 1968) model in which demand between a pair of zones (i and j) is estimated as a multiplicative function of the activity and socioeconomic variables at each of those zones, and the level-of-service attributes of the modes serving them, as shown in the following equation:

$$T_{ijk} = \phi_k (P_i P_j)^{\theta_{kp}} (I_i I_j)^{\theta_{kl}} \prod_m \left[\left(t_{ij}^m \right)^{\alpha_{km}} \left(C_{ij}^m \right)^{\beta_{km}} \right]$$

In the above equation, P_i and P_j are population or other surrogates of trip generative characteristics in zones i and j , respectively; I_i and I_j are employment or other trip attractive characteristics; t_{ij} and C_{ij} are travel time and travel cost between i and j by mode k ; $k \in [1, m]$, respectively; and ϕ_k , θ_{kp} , θ_{kl} , α_{km} , β_{km} are parameters of the model. Specifically, θ_{kp} and θ_{kl} are demand elasticities with respect to population and income, respectively; and α_{km} and β_{km} are demand elasticities with respect to time and cost of travel, respectively (they are direct elasticities when $k = m$ and cross-elasticities otherwise).

For transit ridership prediction, the above framework may be used to estimate stop-to-stop (origin stop to destination stop) ridership flows as a function of the catchment area characteristics of the origin and destination stops and the transit service characteristics between the stops. Such a framework helps not only in estimating the stop-to-stop ridership but also in estimating the revenues earned from ridership. However, many direct demand models of transit ridership focus only on trip generation for transit without considering the spatial distribution of those trips. These are typically in the form of route-level or stop-level ridership models. Route-level models relate ridership to service characteristics at the route-level. Some of the route-level models are designed to relate ridership and service characteristics for specific route segments defined by fare-levels (Peng et al., 1997).

Although service changes typically occur at the route level, ridership on a route varies across the different city zones that the route covers. To consider variation in ridership along a route, stop-level models may be considered. These models relate boardings and

(or) alightings at each transit stop to the catchment area characteristics of that stop (Chu, 2004; 2007; Polzin et al., 2011; Cervero et al., 2010; Gutiérrez et al., 2011; Chakour and Eluru, 2016). Such models make it possible to consider the influence of stop-level infrastructure, amenities, and the population and land-use around the transit stops. Separate models may be developed for boardings and alightings as the influence of service and catchment area characteristics can be different for boardings and alightings. Stop-level models may also be further disaggregated by the routes serving the stops, as route-stop models (Mucci and Erhardt, 2018) in which both route-level service and stop-level catchment area characteristics can be used to explain the stop-level boardings or alightings. Note that stop-level models also allow one to quantify and analyze transfer trips (if such data is available) separately from direct trips.

Transit services in many cities are differentiated into general, subsidized, or luxury categories, with each of these services differing in convenience and comfort, frequency, fare, and in the subset of stops served along a route. In such cases, modeling by service types might be a consideration. Of course, modeling disaggregate, stop-route level ridership separately for different types of services warrants the need to consider competition and complementarity between different services as well as competition or complementarity relationships among different routes in the network.

It is worth noting here that stop-level transit trip generation models are more commonly used than either route-level trip generation or stop-to-stop ridership flow models. Since revenue forecasting is an important reason for transit ridership forecasting, the stop-level ridership forecasts may be used for subsequent estimation of stop-to-stop ridership flows by route and service type or fare class.

Design Considerations for Transit Ridership Forecasting Models

Many considerations go into designing and building an effective transit ridership forecasting model. These include:

- determining the temporal and spatial resolution at which ridership is modeled,
- addressing the complementary and competitive nature of service along different routes,
- treating transfers separately from direct boardings or alightings,
- addressing the interdependency between transit ridership (demand) and service (supply),
- incorporating the different factors that influence ridership, and
- determining the type of mathematical/statistical models to be used.

Each of these model design considerations should be guided by a combination of theoretical as well as practical factors, such as data availability and simplicity for easy usage and explainability. Some of these design considerations are discussed in the remaining section.

Temporal Resolution

The purpose of prediction and data availability guides the temporal resolution of the model. For real-time operational planning purposes, such as provision of on-demand last-mile services, temporal intervals of 15 minutes to 1 hour are useful. While it is desirable to have fine temporal resolution, such as minutes, for purposes such as crowding estimation for real-time operational planning, it is important to have access to real-time sensor data on crowding for such purposes. Models for different time-of-day periods, for example AM peak, AM off-peak, mid-day, PM peak, evening, and night, may be used for near-term planning purposes such as schedule and route structure changes, and fleet maintenance scheduling. Predictions by days of the week, or broadly by weekdays, weekends, and public holidays, are useful for updating weekly schedules and service plans as well as for all of the above-mentioned purposes. For medium to long-term applications, such as resource allocation or substantial increases in bus fleet size, monthly or annual demand may be predicted.

Spatial Resolution

Predicting transit ridership at the typical traffic analysis zone (TAZ) resolution does not provide helpful information to transit agencies for service planning and operational purposes. As discussed earlier, modeling ridership at the route-level, route segment-level, stop-level, or between origin and destination stops is more useful. However, modeling ridership at finer, stop-level spatial resolution is associated with its own challenges and uncertainties. First, closely spaced stops sometimes have overlapping catchment areas. Besides, ridership data collection in many transit systems happens at a fare-stage or fare-segment level, where the number of boardings (or alightings) at a cluster of consecutive stops on a route are aggregated into those of a designated stage-stop. Since fare setting and issue of tickets to riders typically happens at a stage-to-stage aggregation, ridership data is also collected at a stage-level. Therefore, it might be pragmatic to model stage-level boardings or alightings, or stage-to-stage ridership, than to do so at a disaggregate stop-level. However, the analyst will have to disaggregate stage-level catchment area characteristics to stop-level for stop-level ridership prediction, as stage-level ridership is too aggregate to include meaningful stop-level characteristic variables. Additionally, ridership at spatially proximate stages or stops and on a same route might be correlated due to the influence of unobserved factors that influence ridership at these stages (or stops). Considering these issues can potentially improve model

Figure 1 Illustration of ridership-service interactions between complementary and competing routes.

predictions. For example, when linear models are used to model stop-level ridership, [Cervero et al. \(2010\)](#) suggest using hierarchical linear models that account for correlations among stops belonging to the same route.

Complementary and Competing Routes

Service along different routes in a transit network can be competing or complementary. Routes, or portions of routes, that share the same catchment area and serve the same set of origins and destinations compete. For example, two routes that run parallel to each other for any section compete for passengers along that section. In a set of competing routes, service improvements on one route takes away some ridership from the other routes. Therefore, ridership models need to accommodate that predicted increases in ridership on a route is not solely due to new riders attracted to the system but also due to drawing some riders from other routes. Complementary routes are those among which people transfer to get to their destination. The increase in ridership due to service improvements on one route will bring about an increase in ridership on its complementary routes. [Fig. 1](#) below illustrates some of these relationships (also, see [Peng et al., 1997](#)). When modeling transit ridership, it is important to take such substitutive, competitive and complementary effects into account.

Competing and complementary relationships can exist within a same form of transit (for example, between different routes or service categories of a bus service) or across different forms of transit (e.g., between metro and bus transit routes). Of course, such relationships exist between transit and other modes of travel as well. For example, app-based on-demand mobility services can potentially compete with or complement transit systems depending on the spatial and temporal coverage of their services vis-à-vis the transit network and schedules. Therefore, it is important to consider such relationships not only within a transit network but also across different networks and travel modes.

Transfer Boardings and Alightings

Transfers are inevitable in large-scale transit systems. Therefore, not all boardings (alightings) at a stop are due to trip generative (attractive) characteristics of the stop's catchment area. Since the catchment area characteristics do not influence the number of transfers at a stop, modeling transfer boardings (alightings) together with those of direct boardings (alightings) will lead to biased estimation of the influence of service and catchment area characteristics on transit ridership. Therefore, it is important to estimate transfers separately from direct boardings and alightings. This can be done by developing separate models for direct boardings and alightings and transfers ([Chu, 2007](#)). Alternatively, transfers can be estimated at the transit assignment stage after estimating direct boardings and alightings, and the spatial distribution of trips due to direct boardings and alightings.

In several transit systems, a challenge with separating transfer boardings (alightings) from direct boardings (alightings) is that the data collection does not differentiate between the two. Then it becomes necessary to collect additional information on the spatial and temporal distribution of the proportion of boardings (alightings) that are transfers. Such information needs to be used to separate transfers from direct boardings (alightings).

Interdependency Between Demand and Supply

The number of boardings and alightings at bus stops, or the number of riders on a bus route are indicators of transit ridership or demand. Bus frequency or headway on a route, seat miles operated, number of seats per bus, and daily service span are different indicators of the service or supply variables.

It is worth noting here that ridership and service are interdependent. Ridership tends to increase in response to an improvement in service. Sizeable increase in ridership is, in turn, catered to by a consequent increase in service. Besides, some routes have a greater level of service than others because of anticipated greater level of ridership along those routes. For increasing the accuracy of transit ridership prediction, it is useful to consider such mutual interdependency or endogeneity of transit ridership and service attributes. Models that do not account for this relationship overestimate the influence of service improvements on ridership ([Peng et al., 1997](#); [Rahman et al., 2019](#)).

Simultaneous equation models may be used to account for endogeneity between transit demand and supply. [Peng et al. \(1997\)](#) build such a model for Portland's Tri-Met transit agency operations in which major service and route changes occur once a year while minor service and route changes occur whenever needed. Simultaneous transit demand and supply equations for such situations are represented as:

$$R_{iz}^d = F(S_{iz}^s, X_{iz}^d)$$

$$S_{iz}^s = F(R_{iz}^d, R_{-1i}, X_{iz}^s)$$

in which R_{iz}^d and S_{iz}^s are transit ridership (demand) and level of service (supply), for route i in fare zone z . R_{-1i} is the ridership in the previous planning period. X_{iz}^d is the vector of other variables that explain demand. X_{iz}^s is the vector of other variables that explain supply based on the transit operator's decisions. In addition to the above two equations, they also consider another equation to represent demand for other competing routes. The three stage least squares (3SLS) method is used to estimate the parameters of the above simultaneous equations model system as all the endogenous variables under consideration are treated as linear. [Chu \(2007\)](#) states that stop-level models address simultaneity, as simultaneity breaks down at the stop level with service decisions being made at the level of the route. However, even in stop-level ridership models, there is value in considering simultaneity between route-level service characteristics and stop-level ridership for all stops on a given route.

Factors Influencing Transit Ridership

The ridership attracted to transit systems depends on the following two broad factors: (1) external (or exogenous) factors that the transit agency cannot control (at least in the short-term), such as population demographics and spatial land-use of the study area and (2) internal (or endogenous) factors that the transit agency can try to control such as the spatial, temporal, and operational characteristics of the transit service ([Taylor et al., 2009](#)). While a transit agency might not be able to control the external factors, the agency will benefit from monitoring them, anticipate their possible impacts on transit demand, and devise strategies to mitigate or leverage them to their advantage. The external and internal factors together determine transit ridership in the form of two major types of accessibility of the transit system: (1) accessibility of the transit system from a patron's origin or destination; that is, access to population and activity locations within the transit stop's catchment area, and (2) accessibility or connectivity provided by the transit system to major population and employment locations. A brief summary of various factors influencing transit ridership is presented next. In addition, a brief discussion is provided on the factors that influence ridership but not typically considered in direct demand models.

External or Exogenous Factors Influencing Transit Ridership

The exogenous factors influencing transit ridership are listed as follows:

- *Socio-demographic characteristics* of the study area population such as age, gender, race, ethnicity, citizenship or immigrant status, education, employment, income, vehicle ownership, and population attitudes and perceptions;
- *Land-use characteristics* of the study area such as population density, spatial structure and distribution of employment locations, and other trip generators such as entertainment or tourist locations, hospitals, and educational institutions;
- *Attributes of competing modes* such as ownership costs of private modes and usage costs such as gasoline prices, toll prices, maintenance costs, parking availability and pricing; presence of app-based ride hailing modes and the cost and ease of travel by those modes; and commuter travel benefits from employers such as shuttle services and subsidies in transit fares or parking fees;
- *Travel conditions* that include climate and weather patterns, traffic-congestion levels, and disruptions; and
- *Transportation and land-use policies, and funding initiatives* such as zoning regulations, transit-oriented development, air quality mandates, auto emission standards, and state transit funding for capital and operating expenditures.

Internal or Endogenous Factors Influencing Transit Ridership

The endogenous factors may be categorized as follows:

- *Spatial characteristics* such as network coverage, route structure (that is, the extent of transfers, and of competition and complementarity among different routes), stop location and spacing, integration with other modes through feeder services, access and egress infrastructure for intermodal and last-mile connectivity.
- *Temporal characteristics* such as transit frequency, reliability, duration of service, origin-to-destination in-vehicle travel time, waiting and transfer time, access and egress time.
- *Operational characteristics* such as fare structure, ticketing integration, scheduling strategies, and operation of transit priority lanes and signalization.
- *Perceptual characteristics* such as ride quality, comfort, cleanliness, reliability, affordability, safety and security, and the overall level of customer service ([Outwater et al., 2013](#)). Some of these characteristics are determined by factors such as maintenance, extent of crowding, likelihood of denied boarding, provision of real-time information and passenger trip planning applications, on-time arrival, and travel time variance. They are also determined by the effectiveness of infrastructure and procedures for safety and

security. Station or stop-level attributes such as lighting, ventilation, cleanliness, shelter from weather, comfortable waiting, and seating also influence the perception of transit service. Additionally, ease of access to services, safety and surveillance, in-station patron assistance, and ease of buying tickets and passes determine travelers' perceptions of transit service.

Accessibility of the Transit System

The more population and activity centers a transit system is accessible to, the more would be its ridership. The following variables may be used to characterize accessibility of the transit system:

- population density and demographics (defined by income, car ownership, age, gender, etc.) around transit stops or routes within an acceptable walking distance;
- land-use and economic activity around stops or routes in the form of employment in different sectors, measures of activity such as floor area at major trip generators including educational institutions, hospitals, and malls; and
- Measures of connectivity of the transit system to locations that are not accessible by walk, such as connectivity due to first/last-mile feeder services and provision of park-and-ride facilities.

Accessibility Provided by the Transit System

The more activity locations or destinations that a transit system provides access to, the more would be its ridership. Such accessibility can be measured in the form of connectivity of a transit stop (or a route) to various destinations in the network. Stops or routes that offer access or connectivity to a larger number of destinations within a shorter time duration are likely to attract greater levels of ridership. This depends on: (1) the spatial structure of land-use in the study region, (2) the transit route network structure (network coverage, directness of routes, stop location and spacing, ease of transfer among different transit routes), (3) temporal characteristics of transit service such as frequency, reliability (on time arrival performance, travel time reliability), and duration of service, and (4) integration with other modes through feeder services, access and egress infrastructure, etc. for intermodal and last-mile connectivity to enhance transit catchment area.

Note that accessibility of a transit system, discussed in the earlier section, is different from the accessibility provided by the transit system, as discussed in this section. In a stop-level ridership model, for example, the former is a measure of how much population and employment is a given stop accessible to whereas the latter is a measure of how many other destinations can one access from the given stop.

Factors Not Considered in Direct Demand Models

Many direct demand models do not consider the influence of several factors on ridership. One such set of factors is traveler perceptions and attitudes. Research is underway on ways to assess traveler perceptions of transit services (e.g., reliability, safety, comfort, cleanliness, affordability, amenities, customer friendliness) as well as to consider the influence of traveler attitudes (e.g., environment-friendliness and status-seeking behavior) in promoting transit ridership (Outwater et al., 2013). Ridership forecasting models must be enhanced to consider these factors. Equally important is to consider the role of contemporary issues such as that of the current pandemic on travelers' perceptions and its influence on public transit ridership.

Pricing is not included in many ridership models. Transit fare is an important determinant of transit ridership. However, it is challenging to capture the effect of fare changes (in transit or in its competing modes) in direct demand models. This is because of the lack of variation in prices in the time range of typically available transit ridership data. Most studies are conducted using data for a couple of months to at most a year, and transit fares may not necessarily be revised in that duration. Yet, transit agencies need to understand the influence of changes in price structure (not only of the transit systems but also of other modes) on transit ridership.

Finally, it is not easy to incorporate the influence of changes in level-of-service characteristics of other competing modes in direct demand models. In fact, most implementations of direct demand models for transit ridership forecasting do not consider competition with other modes. One way to overcome these limitations is to integrate information from disaggregate mode choice models, which capture the influence of pricing and characteristics of other modes. For example, measures such as log-sum variables from a logit-based disaggregate mode choice model can be used as explanatory variables in a direct demand model. Doing so might help embed the influence of pricing as well as the characteristics of other modes on aggregate level transit ridership.

Model Structure

A variety of different statistical/econometric model structures may be used to model transit ridership. The choice of the model structure depends on the spatial and temporal resolution at which ridership is modeled, the nature of available data, the various model design considerations (as discussed in earlier sections), and a trade-off between model complexity and ease of application.

Data for transit ridership prediction can be of the following types:

- time series or historical data of ridership of a city or an independent transit region;
- real-time data for 1-step (e.g., 15 minute) ahead predictions for arrivals at stations;
- cross-sectional data spanning multiple locations (e.g., bus stops) in the same time duration and
- panel data of a same set of locations from multiple time periods.

Table 1 Summary of transit ridership models used in the literature

<i>Author(s)/ Year</i>	<i>Model approach</i>	<i>Data</i>	<i>Spatial resolution</i>	<i>Time duration for the model</i>	<i>Explanatory variables used in the model</i>
Peng et al. (1997)	Simultaneous equation model	Tri-Met (Portland) service area	Route-segment (by fare zones)	Morning peak, midday, afternoon, evening, and night	Transfers, service duration, headway, service supply, population, income, employment density, parking spaces, previous year ridership, percent population in overlap area of route buffers, frequency, route typology
Chu (2004)	Poisson regression model	Jacksonville, Florida	Stop level	Average weekday boarding	Catchment area variables: median household income, jobs, zero vehicle households, share of persons of different age, gender, race; Composite TLOS variable (transit service, stop catchment area characteristics, stop level pedestrian environment) pedestrian factor, persons and jobs up and downstream without transfer, trolley stop, TLOS stops (four stops at an intersection)
Chu (2007)	Poisson and negative binomial regression models	Jacksonville, Florida	Stop level (direct and transfer boarding models)	Weekday morning and afternoon peak, weekends	Direct boarding models: natural log of frequency, daily service span, workers, population in origin buffer, vehicle ownership, service and commercial employment, park-n-ride lot spaces, stop on route typology, accessibility to population and employment
Cervero et al. (2010)	Hierarchical linear regression	BRT services in Los Angeles county	Boardings (and /or exits) at a stop/station	Daily recordings for October 2008	Service attributes, location and neighborhood attributes, bus stop attributes

Mucci and Erhardt (2018)	Linear regression model	GTFS data (2009) from MUNI transit system operating in San Francisco	Route-stop level model	Daily average number of bus/rail boarding and alighting	Demand variables: employment near stop, income, housing and population density, share of households with zero vehicles and on-street parking cost. Supply variables: average number of buses, number of stops within walking distance of route-stop, terminal stop of bus line, route configuration, reliability.
Rahman et al. (2019)	Simultaneous equation model	Greater Orlando region	Stop level	Average weekday boarding, alighting, and headway	Stop level attributes, transportation and transit infrastructure variables, built environment and land use attributes, demographic and socio-economic variables in vicinity of the stop: income, vehicle ownership, age and gender distribution.

In naïve time-series models, a curve is fitted to the historical ridership data and projected to obtain estimates for the future. It may also be regressed against explanatory variables such as jobs, income, fare, and fleet size (McLeod et al., 1991). Cross-sectional data across bus stops or routes of a single city is widely used to estimate transit ridership (Chu, 2004; 2007; Peng et al., 1997; Cervero et al., 2010; Chakour and Eluru, 2016). Panel data models are used to recognize that the data may have come from multiple time periods from the same set of locations (Rahman et al., 2019).

Although intended for continuous data, linear regression models are often used in estimating direct demand models of transit ridership counts. Poisson and negative binomial models are used to recognize the count data nature of transit ridership. In the case of over-dispersed (variance larger than mean) data, negative binomial models are preferred. It is also possible to use ordered response models, where ridership is grouped into different levels such as low, moderate, high, and very high.

Regardless of the type of the dependent variable used for modeling ridership, considering dependencies in ridership among proximate stops would need one to incorporate spatial correlations (Chakour and Eluru, 2016; Sarlas and Axhausen, 2014). Further, accommodation of endogeneity between demand (ridership) and supply (service) variables needs econometric approaches such as three stage least squares or simultaneous equations (if the demand and supply variables are treated as continuous) or control function approaches (if the variables are analyzed using non-linear models). The past decade has witnessed the use of machine learning, particularly for predictions using near real-time data (Koutsopoulos et al., 2019) such as crowding prediction (Noursalehi, 2017).

The reader is referred to **Table 1** for some examples of different transit ridership models used in the literature, their spatial and temporal resolutions, and the variables used to explain ridership in those studies.

Emerging Trends and Future Directions

The emerging mobility landscape, particularly the market penetration of on-demand ride hailing and ride sharing services, the rapid rise of automation in transportation, and the influences of information and communication technologies on travel influence travel behavior and transit ridership. Some notable trends with anticipated influence on transit ridership include the following:

- the availability of real-time passenger information and trip-planning apps,
- automated and integrated fare collection and payment systems,
- use of app-based on-demand Mobility as a Service (MaaS) modes for enhancing first- and last-mile connectivity of fixed route transit systems, and
- technology-assisted safety features such as in-vehicle cameras and remote monitoring.

Unlike the socio-demographic and land use changes (and their influence on transit ridership), which occur relatively slowly, some of the above-mentioned factors have altered travel behavior in a very short time and will have a substantial influence on transit ridership. Transit ridership forecasting models must be enhanced to accommodate the influence of such trends.

Many transit systems are now equipped with automated vehicle location (AVL) and automated fare collection (AFC) systems that generate large amounts of historical as well as real-time data on transit ridership and system performance. There is scope for combining such “big data” sources with traditional data sources for understanding and predicting ridership. For example, ridership and AVL data can be combined to distinguish between locations of designated or informal stops for passenger boarding or alighting and stops due to traffic congestion. There is also scope for developing transit ridership models combining land-use, weather, events, and other big data sources. Existing sources of big data often do not provide information such as socio-demographic characteristics of passengers. Integrating data from small surveys would be a potential direction to undertake for efforts needing such information (Zannat and Choudhury, 2019).

Spatial Mismatch, Job Access, and Reverse Commuting

Since the latter 20th century, transportation policymakers, planning practitioners, and researchers have maintained steady interest in the impact that access to jobs may have on the employment outcomes of individuals—particularly economically or socially disadvantaged individuals. To what extent, if any, does the spatial arrangement of employment and housing opportunities support or hinder one's ability to find and keep a job? Do restrictions on residential mobility resulting from racial discrimination diminish job access and employment? How important are challenges in transportation and commuting to employment outcomes? Such questions are persistent concerns in an abundant literature examining such related topics as spatial mismatch, job access, reverse commuting, jobs-housing balance, and transportation mismatch.

Interest in these areas is rooted largely, but not exclusively, in the context of U.S. transportation planning in the latter 20th century, and in the distinctive spatial patterns of postwar American metropolitan growth and employment of persistent residential segregation. This essay traces the emergence of these concepts in the wider domain of urban policy and planning and highlights how practitioners and scholars have continued to observe and measure them and to debate their salience.

Emergence of the Spatial Mismatch Hypothesis

Policymakers and scholars first began to consider the importance of potential linkages between transportation and employment in the 1960s. Economist John Kain articulated the first threads of what is known as the spatial mismatch hypothesis in a seminal conference paper (1965, 1992). He aimed to explain the lower levels of employment among American Blacks concentrated in the urban core and Blacks' underrepresentation in employment zones far from Black urban enclaves.

Kain highlighted how racial discrimination in the housing market limited Blacks' ability to exercise residential choice. This not only led Blacks to be spatially concentrated in "urban ghettos" but also consequently impeded their ability to share in the employment growth spreading from cities to suburbs at the time. The spatial mismatch between the "the Negro ghetto" and the locations of expanding employment cost Blacks jobs, Kain argued.

Kain's ideas about spatial mismatch gained purchase in wider discussions of urban policy in the mid-1960s to early 1970s. During this period, an unprecedented wave of Black-initiated urban rioting and violence erupted in hundreds of cities across the U. S., symbolized most vividly perhaps by the Watts Riots in Los Angeles (1965), the Newark riots (1967), and the Detroit riots (1967). Though specific causes of individual riots were debated, cumulatively the riots were important means through which urban Blacks protested the fundamental conditions of ghetto life. These included high rates of unemployment and rigid residential segregation (Fogelson, 1967, 353).

A Federal commission appointed to study the causes of Black civil unrest pointed in part to the challenges of the urban ghetto and its physical isolation from wider economic opportunity (U.S. Kerner Commission, 1968). Federal and state policymakers directed attention to how transportation might better connect urban Blacks with suburbanizing jobs. Interest in "reverse commuting" first arose in this context (Rosenbloom (1992).

As post-WWII employment and population growth concentrated increasingly in suburbs, many central city workers had to seek jobs in the suburbs or further exurbs. Construction of the Interstate Highway System and rising levels of household automobile ownership enabled employers to establish themselves in the suburbs, which would quickly transition from mere bedroom communities dependent on central city jobs to centers of employment and commerce in their own right (Muller, 2017).

At the same time, holdover racial covenants and exclusionary zoning present in many suburban communities precluded Blacks from establishing residence there (Whittemore, 2017). Further, discriminatory mortgage lending practices like redlining made it difficult for blacks to secure legitimate home loans from government lending programs. Consequently, many turned to exploitative "contract sales" to purchase their own urban homes, albeit on highly unfavorable terms. Together, these and other practices all but

ensured that most American suburbs remained white, that few Blacks would amass the equity needed for home purchases, and that most Blacks would remain in inner city neighborhoods, far from where new jobs were being added.

Serving the Reverse Commute

Access to suburban jobs was essential to un- and underemployed inner city residents, but it was also potentially challenging. For workers unable or unwilling to move beyond the city to follow the jobs, reverse commuting from central city to suburb was one answer. Reverse commutes accounted for roughly 7% of all trips in the 1960s. Yet, reverse commutes to suburban job locations would typically be longer in distance than CBD-bound commutes and would require more time and expense. Dispersed suburban job sites were also less likely than urban jobs to be served by public transit. Many workers turned to the private car, if they had the means to do so (Rosenbloom, 1992).

Acknowledging these challenges, the Federal government sponsored a number of demonstration projects in the mid- to late 1960s to establish better transit links between the inner city and suburban jobs. Well documented by Rosenbloom (1992), examples included the Shirley Highway Express Bus in Washington D.C. and the Chicago express bus route carrying airport employees from the end of a rapid transit line to O'Hare.

Still, these demonstrations generally yielded modest benefits, revealing how difficult it was to improve employment outcomes for inner city residents through transportation. Project assessments suggested that a range of factors beyond transportation might be keeping inner city minorities from better suburban jobs, including job search and dissemination practices, high employee turnover, mismatch between vacancies and applicant skills, not to mention naked discrimination. It was also hard for local transit operators to make reverse commute service operationally viable. Traditional transit operators already faced declining ridership and rising costs, and they struggled to serve reverse commutes given "the sprawling automobile orientation of suburban . . . work locations, [and workers'] shift times, and overtime requirements" (Rosenbloom, 1992, 11).

By the 1980s, direct Federal efforts to address unemployment through transportation had diminished. Instead, though transportation was outside of their mission, not-for-profit social and human service agencies increasingly provided free or low cost transportation to connect inner city residents with suburban jobs. Private employers also funded and coordinated employee shuttles to suburban job sites, acting through nonprofit Transportation Management Associations (TMAs). Tenant management associations organized transportation services helping public housing residents to access jobs. To a limited extent, some public transit operators provided feeder buses to and from suburban rail stations and other niche services to support reverse and off-hours commutes. Most of these nonprofit and transit operator services, however, had limited success in reversing high joblessness among inner city residents (Rosenbloom, 1992).

In the 1990s, as federal welfare reform transitioned recipients of public aid into local labor markets, the U.S. government began to encourage local collaborations to enhance job access for disadvantaged urban populations via transportation. The signature Job Access Reverse Commute (JARC) program, which remained in place through 2012, offered Federal grants to support a range of planning, capital and operating costs for public transit projects connecting to suburban workplaces; funds for reverse commutes services and travel vouchers were available too. Projects demonstrating collaboration and cost sharing among state and regional transportation agencies, transportation providers, county welfare and employment agencies, and other community stakeholders were highly favored.

Experience with JARC and earlier reverse commute efforts suggested that community transportation services and were not enough to improve employment outcomes for unemployed and minority inner city residents. JARC successfully stimulated nontraditional partnerships to address transportation needs of low-income job seekers, but the diverse organizational perspectives among collaborators made it difficult to identify and plan for the transportation needs of targeted groups (Blumenberg, 2002). More significantly, JARC funds could be used only for public transportation, not for automobile-related expenses (Blumenberg and Schweitzer, 2006). Program observers highlighted this limitation, heralding rising skepticism that public transit could adequately bridge the spatial mismatch between inner city residents and spatially dispersed job opportunities.

Emerging demographic trends further suggest limited potential for public transit in general or reverse commute options in particular to improve employment outcomes for low-income populations. Fast growing poverty in American suburbs since the 2000s has captured the attention of policymakers and planners. Poverty in the U.S. has traditionally been associated with the urban core and rural communities, and it continues to expand in those places; however, the number of suburban residents living in poverty has increased at a starkly faster rate in the 21st century. Expanding suburban poverty and continuing decentralization of jobs together pose new transportation challenges. Most transit systems provide central city-oriented hub-and-spoke service and do not provide the suburb-suburb connections important for reaching dispersing jobs (Kneebone, 2017). Such trends may add to calls for enhanced automobile access for low-income job seekers.

Expanding, Evolving, and Challenging Spatial Mismatch

In the decades since Kain first articulated the theory, researchers have questioned the extent to which poor labor market outcomes experienced by inner city residents, particularly those of color and/or low income, are attributable to "spatial mismatch." Most researchers have agreed that the spatial disconnect between job rich areas and urban neighborhood residents who need those jobs was real. Still, many have disagreed about the relative importance of spatial mismatch and used different approaches to measure it.

Some have viewed the emphasis on spatial causes of poverty as downplaying the role of racial discrimination. To understand Black urban unemployment, Ellwood emphasized, “It’s not space, it’s race” (1983). Other work has questioned whether an emphasis on race obscured important insights into the operation of labor markets, particularly the operation of those markets in the face of suburbanizing employment and housing discrimination. How do workers with certain characteristics and residing at a certain location ultimately match with jobs with their own specific characteristics and locations?

Others concluded that mismatch had been oversold as a locational problem and that other reasons for poor employment outcomes among blacks and low-income groups were important. Declines in employment rates of blacks and black males in the 1970s should be viewed in the context of “industrial shifts, technological change, declining relative quality of black education, [and] weakening antidiscrimination efforts by government” (Holzer, 1991, 108).

A prominent stream of research has suggested that low-income inner city residents are challenged less by the spatial mismatch distancing them from jobs, and more by the “transportation mismatch” or “modal mismatch” preventing them from bridging the distance to work sites, far or near. Job seekers who lived in job-poor neighborhoods and who relied on public transit experienced significantly less access to employment *because of* long and unreliable transit commutes. Studying welfare participants in Los Angeles, Blumenberg and Ong (2001) found that—despite suburban employment growth—the bulk of jobs were actually located *in the central city*; yet, residents of job-poor neighborhoods had trouble accessing those jobs if they depended only on public transit.

Further insights called attention to the diversity of settings in which welfare recipients and other low-income job seekers live. Traditional conceptualizations of “spatial mismatch” focused narrowly on the central city. What about low-income households and job seekers living in older inner-ring suburbs and non-urbanized areas and challenged by low concentrations of jobs? Such settings made access to private vehicles important for employment. Other transportation and policy approaches might be appropriate as well, including dynamically routed transit, express buses, as well as local economic development (Blumenberg and Hess, 2003).

Such insights catalyzed calls for programs to increase automobile access for welfare recipients and low-income job seekers. Later research substantiated such concerns. One longitudinal evaluation of U.S. welfare recipients transitioning to employment found that access to an automobile was a better predictor of subsequent employment than was access to public transportation or housing assistance (Blumenberg and Pierce, 2017). Automobile access also proved important in a longitudinal study of the U.S. government’s landmark Moving to Opportunity program, which provided housing assistance for participating low-income households to move out of low-income neighborhoods in order to improve their employment outcomes. While housing mobility proved inconsequential, households that gained or retained access to an automobile during the study period were more likely to be employed, suggesting that “having a car provides multiple benefits that facilitate getting and keeping a job” (Blumenberg and Pierce 2014, 52). Further, transit access did not necessarily produce job gains, though it seemed to help already employed individuals retain their jobs.

Another longitudinal study by Hu (2015) examined the Los Angeles region between 1990 and the late 2000s and concluded that when job accessibility is measured by the spatial distribution of jobs and job-seekers traveling by car, that the inner-city poor in fact do not face spatial mismatch and that they enjoy higher job accessibility than most suburban poor (2015). Accordingly, she questions whether traditional answers to spatial mismatch, including moving people to the suburbs, bringing jobs to the inner city, or providing mobility options will be effective (Hu, 2015, 44). Conversely, a separate 2018 study of person-specific job accessibility and the duration of joblessness provides compelling support for the mismatch hypothesis, suggesting that scholars will continue to debate how best to state and test for the spatial mismatch problem (Andersson et al., 2018)

Measuring Spatial Mismatch

In the abundant literature around spatial mismatch, researchers have used a variety of approaches to identify ‘mismatch’ and measure job access. Houston provides a thoughtful summary (2005). Early research into spatial mismatch used simple measures of residential segregation to suggest that, where a highly segregated community also experienced high unemployment, spatial mismatch was at work. Subsequent studies aimed to account for employment access. Researchers made cross sectional comparisons of average commuting times and distances for Blacks and Whites, and observed mismatch where average commute times (or distances) for Blacks exceeded those for Whites. Critics, however, suggested that the average commute times and distances approach failed to account for different travel modes used by Blacks and Whites, for income differences between the two groups, or for their different abilities to trade off housing costs and proximity to employment. Alternatively, some studies have compared the average wages of African-Americans in the city with those in the suburbs, though data limitations have made this difficult to do well.

Studies in the 1990s began to estimate measures of job proximity, a clear step forward though one still limited by data and technical constraints (Houston, 2005). For instance, it is difficult to capture proximity accurately, as measures must take account of competition for jobs, travel modes and mode-specific travel times, as well as the labor market segment of interest.

Houston’s review provides perhaps most clearly distills the basic direction for spatial mismatch research. “In methodological terms, the first, and inescapable, stage in testing the spatial mismatch hypothesis is to measure the extent of spatial mismatch by examining the location of jobs in relation to the location of people, differentiating between labor market segments in terms of occupation, skill level, gender, race, and those with and without access to a car. The second stage is to determine what effect spatial mismatch has on these groups in terms of unemployment and wage levels” (2005, 430–431).

Job Access

Measuring job accessibility has been a key focus of the spatial mismatch literature and has also attracted attention from the fields of urban sociology, regional science, and geography in studies of the geography of opportunity or “opportunity structures” across multiple dimensions, including labor. Such sustained interest in job access has yielded numerous innovations and improvements in its measurement.

The earliest approaches to gauging job access used gravity-based and cumulative opportunity accessibility measures, derived for a given spatial unit, such as a census tract or traffic analysis zone (TAZ). Cumulative opportunity measures are perhaps the simplest; these tally the number of employment opportunities that reachable within a defined commute-shed, based on time or distance. All destinations that fall within the commute-shed threshold contribute equally to accessibility. Gravity-based measures typically estimate job accessibility by calculating the sum of employment opportunities reachable within a travel distance or time threshold, discounted by an impedance factor representing the generalized cost of travel, including time or distance. Thus, employment opportunities count unequally in gravity-based job accessibility (El-Geneidy & Levinson, 2006; Handy and Niemeier, 1997).

Contributions to the spatial mismatch literature have developed increasingly specific measures of job access. By finely-tuning job accessibility measures, researchers have aimed variously to more accurately represent workers or job-seekers, the locations of travel origin and destination, travel modes used, and job opportunities of interest (e.g., by wage-level or economic sectors).

Transit-based job accessibility has been a particular point of interest. Blumenberg and Ong (2001), for instance, measured levels of access for (largely female) welfare recipients in Los Angeles specifically to low-wage, feminized jobs, reachable by automobile and by public transit. More recently, others have sought to document patterns of transit usage to low-wage employment zones by workers in different occupations, finding that different occupations align with different patterns of transit usage (Legrain et al., 2016). The emergence of General Transit Feed Specification (GTFS) data, published by growing numbers of transit properties and capturing schedule and geographic information in a common format, has enabled additional measurement advances, including more universal assessments of job access by transit. Such data have been used to derive route-level accessibility measures for different demographic groups (Karner, 2018), to examine how transit network changes impact job access of demographic subgroups (Swayne and Miller, 2018), and to account for temporal variation in transit accessibility over a 24-h period (El-Geneidy et al., 2016). Other advances in accessibility measurement include person-specific job accessibility, in contrast to conventional cross-sectional approaches that aggregate individuals by neighborhood (Andersson et al., 2018).

Spatial Mismatch in Other Contexts

While concern with spatial mismatch first arose in the context of suburbanizing and segregated postwar America, the topic—and related issues of job access and reverse commuting—has emerged in other national contexts too. Examples mentioned below, while not comprehensive, illustrate the extended interest in mismatch. Recent scholarship has applied the spatial mismatch framework to rapidly urbanizing China. Different urbanization processes in China have not produced the inner same city–suburban contrasts or pronounced income-based residential segregation as are visible in the U.S. However, the spatial concentration of essential services and opportunities in central areas, compounded in importance by residential permitting systems or *hukou*, may be problematic for low-income populations and rural migrants living in peripheral areas. In Britain, a stream of literature related to spatial mismatch emerged in the 1970s to examine the “entrapment hypothesis” that low-income residents of public housing were disadvantaged in the labor market (for an overview, see Houston 2005). Finally, absent the U.S. context of segregation and inequality, reverse commuting by regional rail from central Stockholm to satellite new towns facilitated economic integration as the region transformed from a monocentric city to a polycentric metropolis in the latter 20th century (Cervero, 1998).

The transportation system in our society today is made up of complex large-scale interactions that are driven by behaviors of travelers as they interact with each other and their dynamic environment in a bid to get from one place to the other. Complex systems can generally be explained on a macrolevel, together with their functionality; however, many of the explanatory details are lost. This becomes especially important if improvements or changes to the system are to take place. To explain the concept we can take a laptop computer as an example. You know how to start the laptop, operate it, use it to write text, watch movies, design webpages, develop applications, or even design transport policies. Most of you reading this are probably not concerned how a computer is able to execute the operations a user requests. However, for those curious enough or those that need to perform fundamental changes or improvements to the system, a lower level of understanding is required. On a macrolevel one might want to add additional memory to improve the performance of the laptop. However, to increase the performance of the memory itself, one needs to go to microlevel, to circuit design. Therefore, one can start from a macro perspective, through meso-, to finally arrive at a microscopic perspective, depending on the focus of usage or improvements one wants to be able to perform.

The same analogy can be applied to transportation. As the general users of laptop computers the same applies to everybody stepping out of their homes and using the transport network to travel. Adding road lanes to increase the capacity of the network is similar to adding memory to a computer. Finally, understanding the effects of vehicle or individual behavior on the system shifts the view to the microlevel similar to the circuit design for computers.

This leads us to the first important observation in this chapter: Understanding a system on a macrolevel is in general important and can be useful to both users and engineers; however, complete understanding and possibility to do fundamental changes come from a micro perspective.

In traffic modeling, traditional models have in general been aggregated and have observed travel on a macrolevel. This results in the loss of the link to the individual travelers or vehicles. This is where four-step models, which model traffic flows on an aggregate level between the predefined zones start to exhibit limitations. Microsimulations of traffic and agent-based models of individual travelers tend to overcome this limitation by focusing on individual vehicles and travelers, respectively.

The rest of this chapter will guide you through the microlevel of modeling in transportation, the reasons behind its relevance, and some of the current micro-modeling approaches both commercial and academic. The final section will highlight some of the shortcomings and best practices for the use of simulation in transportation.

The Microlevel in Transportation Simulations

Before we start we need to define two simulation approaches in transportation that will be the focus of this chapter: microsimulation of traffic flows and agent-based models.

Microsimulation of traffic flow considers vehicles as particles on the road links which are moving through the network according to the rules of traffic. These rules include, but are not limited to the following:

- traffic lights, which define whether a vehicle is allowed to cross an intersection
- turning rules defining to which road a vehicle can go on after approaching an intersection
- vehicle separation rules, defining how far apart vehicles need to be at different speeds or congestion levels
- lane changing rules, defining when and how it is acceptable to change the driving lane
- parking rules defining an approach to for example on-street parking spot and maneuvers for parallel, diagonal or perpendicular parking, which can affect the traffic in different ways, etc.

Some of the rules or regulations in traffic are imposed by infrastructure, like traffic lights or turning restrictions, while some are informal like vehicle separation, lane changing or merging behavior. The latter are usually not uniform across the drivers and simulations try to capture this by including stochasticity in their models. The rules and driving behavior explained above are a part of

the rules that define how a driver would behave in the physical world. Traffic microsimulation therefore aims to mimic these rules in the simulated world. Through this, microsimulation allows to study the complex nature of vehicle interaction on road networks and their impacts on a system as a whole.

Each vehicle is also characterized by certain performance metrics, making each vehicle unique in the simulation. Some examples of these metrics include: driving characteristics like maximum speed, acceleration or deceleration, length and width which define the space it occupies on the road, etc.

Vehicle origins, destination, and routes are generally generated externally and assigned to the network, where traffic conditions are then analyzed.

Agent-based models in transportation consider both individual travelers and vehicles on a microlevel. However, in contrast to the microsimulation of traffic, agent-based models are more focused on persons and their behavior than on the vehicles and traffic rules that they are required to follow. Each individual person in an agent-based model is represented by a so called agent. Each agent usually contains a sequence of activities it needs to perform within a certain period of time. This period of time can be hours, days, weeks, or even months. To reach all of the activities an agent has to travel and in this way interact with other travelers and compete for the resources on the transportation network. The resources that travelers compete for can be in the form of space on the road or on the bus, or also for limited number of car-sharing vehicles available in the system.

To allow the agents to make choices in the system based on the state of transportation system and choices of other agents, mode-choice and location-choice models are usually fully integrated in agent-based models.

Each agent, or in a physical world a traveler, contains certain information that makes it unique, as is the case for vehicles in the case of traffic microsimulations. Some examples of the various information an agent can contain is: unique id, age, gender, income, certain preferences or attitudes toward transportation modes, etc. Since agent-based models in transportation are more focused on travelers behavior, they usually model traffic on a higher level, where many of the traffic rules are approximated.

It is also important to note that they can also be combined into a single simulation platform. In this way both vehicles and travelers would be considered as particles that follow certain rules, be it traffic or behavioral. Due to the large complexity of simulating both worlds on a microlevel, these simulations are computational very slow and are currently rarely seen in practice due to this limitation.

Why Microlevel?

Now that we have gone through the differences between the two types of transport simulation, it is essential to understand why they are important.

Before the advent of the car, the speed of individual travelers in densely populated areas was bound to the speed of foot and hoof.¹ As the speed of travel was slow, modeling traffic or pedestrian flows was unnecessary. With the invention of a car, the speed on the roads substantially increased and with their increased affordability the number of vehicles on the roads became substantial. This has consequently created the need for more sophisticated traffic rules. As the experimental approach to test innovative traffic rules, traffic light signaling, or intersection types in different road networks is both time and cost inefficient, a simulation was seen as a better alternative. As the power of computers increased, it allowed for transport planners to develop efficient simulation traffic models. These simulations allow for the analysis of a multitude of design solutions before implementing them in practice, reducing both time and cost.

The progress of technology and an advent of the smartphone has also brought many changes to how people move between points in the network. In recent decades we have witnessed the start of car-sharing and bike-sharing services, followed by ride-hailing, and more recently e-scooter sharing services. Much research has also been focused on automated vehicles and their operations. Aggregated models were just not ready to handle these emerging mobility solutions, as they are neither available at all times like a private car nor are they scheduled like public transport. These services usually cover certain operating areas and their availability is space and time dependent.

Bonabeau (2002) very nicely explained that the main benefit of agent-based models is the capability to model emerging behavior. That is why agent-based models have seen great success in many fields, and not just in transportation. Being able to incorporate new modes of transportation easily and being flexible allows to answer many of the newly arising operational topics in transportation, like relocation of vehicles, dispatching of taxi services (be it automated or conventional), parking constraints, pooling of passengers, route constraints, intermodality, or any combination of the above.

We can also take an example of a transport policy that is already used in practice for some time: the cordon pricing strategy, usually introduced to reduce congestion in city cores. This strategy implements a charging scheme, which makes all or certain drivers pay a toll to enter a city with a car. With aggregated models the impact of this strategy on individuals with different activity patterns or income is lost and thus limits the level of insights we can gain on for instance equity analysis.

This brings us to conclude that agent-based models are necessary when designing transport policies for modern transportation systems as they are more equipped to deal with microconstraints imposed by the emerging transportation modes and research questions we want to answer.

¹ Disregarding a short period of time between the start of the urban trains era and invention of the automobile.

Examples of Microlevel Transport Simulation Models

Microsimulation represents the movements of all vehicles on the road network. These movements, however, can be modeled using different methods. Two more widely used methods are car-following and cellular automata models. Car-following model is a continuous time model of traffic that is based on differential equations. It is potentially very realistic, can model spillback effects,² but is computationally very intensive. Cellular automata similarly to car-following models uses a set of rules to determine the behavior of each vehicle on the road network. It, however, divides roads into cells with two states, empty or occupied, to define whether a vehicle is currently occupying a cell or not. It can still model spillback, and is potentially computationally less intensive than a car-following model.

Agent-based models, on the other hand, tend to use simplified or higher level representations of traffic flow, like volume-delay functions or queue models. Volume-delay functions are used to estimate travel time on the road link based on the demand. They do not model spillback, and are not really realistic, but are computationally very fast. Queue models use queue theory to represent traffic dynamics. They are one of the simplest models that can still represent spillback, but do not model any vehicle behavior inside of the road link.

This section would not be complete without mentioning some examples of the microsimulation and agent-based frameworks. The list below is definitely not exhaustive, but should build a good foundation for further reading.

Some examples of traffic microsimulation software are: VISSIM (Fellendorf and Vortisch, 2010), Aimsun (Casas et al., 2010), Simulation of Urban Mobility (SUMO, Behrisch et al., 2011), and MITSIMLab (Ben-Akiva et al., 2010). All these focus on a more detailed representation of the interaction of vehicles on the road network and use some version of a car-following model. While VISSIM and Aimsun are both commercial software, Sumo and MITSIMLab are fully open-source software developed at DLR³ and MIT⁴, respectively.

Agent-based models are mostly arising from academic work. While some of the approaches to agent-based modeling in transportation have been discontinued for different reasons, many are still around today and some examples of those are: POLARIS (Auld et al., 2016), SimMobility (Adnan et al., 2016), MATSim (Horni et al., 2016), mobiTopp (Mallig et al., 2013), and many others. All these agent-based models also include a traffic simulation part. Polaris uses a variant of a volume-delay function approach, SimMobility utilizes MITSIMLab for its traffic simulation, MATSim uses a queue model while mobiTopp relies on VISUM⁵ for an aggregated traffic assignment. As hinted previously, most agent-based models tend to approximate vehicle interactions on the network for the sake of reducing computational complexity and mostly focus on other aspects of transportation modeling, but some still depend on more detailed traffic simulation like SimMobility.

Agent-based models are often paired or fully integrated with activity-based or land-use models to provide additional features to the user. Polaris uses an activity-based model called ADAPTS (Auld and Mohammadian, 2009) to generate activities for people in the study area, while MATSim has been paired previously with an activity-based model called TASHA (Roorda et al., 2008) or a land-use model simple integrated land-use orchestrator (SILO).⁶ Integrating or pairing activity-based, agent-based, and land-use modes into a single framework can create a powerful planning tool capable of answering many transportation policy questions.

Nothing is Perfect

While microsimulation and agent-based model frameworks can be very powerful they are not perfect as they are in the end both models or approximations of a certain manifestation of the physical world. Therefore, we also have to look at some of the shortcomings of these simulation approaches.

Since the first microsimulation and agent-based modeling techniques in transportation appeared during the previous century, computing power has substantially increased. However, both approaches are still limited by high computational complexity and sometimes slow computing speeds. With new operational questions arising, new transportation modes appearing, and as vehicle-to-vehicle communication is starting to pave its way into traffic systems, these models have to deal with more computational heavy tasks than ever before. Researchers and planners usually overcome this problem by approximating certain parts of the simulation to gain in speed.

Agent-based modeling frameworks are usually very data hungry. Users of these frameworks need to invest considerable time to set up their simulation models. In the process they have to deal with many datasets, their cleaning, processing, and finally incorporating them in the model. When not available, data need to be obtained through surveys or data purchase from commercial providers. Data sources can also come from different time periods, where the time difference between collection points of datasets can be more than a few years. All this implies that substantial work is generally needed to prepare necessary inputs to an agent-based model. Additionally, as data-sources contain errors in itself, input to the models can be of various accuracy. Therefore, one must be careful

² Spillback occurs when downstream road link has reached its capacity so the congestion builds up on the upstream road link.

⁵ www.ptvgroup.com.

⁶ www.silo.zone.

when interpreting the output generated by the model. Possible implications of the input accuracy on the model output and its usefulness be it qualitative or quantitative should be pointed out.

A comparison of performance of different traffic simulation or agent-based modeling platforms is also lacking. Almost no attempts were made to compare the outputs of different models and their forecasting abilities. Agent-based models are already being developed and used for some time, so it is becoming hard to neglect the fact that there are no studies aiming to verify their forecasting power. The powerful features that agent-based models have should be strengthened by a careful analysis of their ability to predict and forecast policy outcomes.

Reproducibility of studies is as well one of the stumbling blocks of simulation. It is very rarely the case that studies conducted with transport simulation software are reproducible, as the chain of steps from input generation to final output is rarely documented in a reproducible manner. This currently decreases the value of simulation outcomes. This decreases the value of the studies performed with simulation tools. To avoid this, one should make sure that input generation process is well documented, data is available for re-use and a clear documentation of steps taken to perform the study is available. This is not a simple task, but one that is necessary to increase the fidelity and reproducibility of simulation studies.

Most simulation tools are not perfect, but even with some shortcomings, these transportation simulation models provide a powerful tool to analyze possible transportation policies.

Final Remarks

Microsimulation of traffic flows and agent-based models are powerful techniques that simulate transportation phenomena observed in the physical world. Both techniques are today used by practitioners and researchers to model changes in the transportation infrastructure and forecast their impacts on the whole transportation system. This chapter provides some of the backbone information on these techniques, why they are important modeling tools, why they are necessary, and some of the shortcomings that you should be aware of. On this you should be able to build upon and extend your knowledge with either the literature provided in the next section or by becoming one of the many users of these techniques.

Introduction

Decision makers (DM)—individuals, households, and firms among others—make several decisions as part of their life cycle. These decisions could be short time decisions such as *what mode of travel to consider to arrive at the next activity location* (for individuals) or long-term decisions such as *what house to purchase* (for a household) or *where to establish a place of residence or commercial enterprise* (for a household or a firm respectively). In understanding these decision processes that are usually discrete outcome variables, researchers across various fields including economics, psychology and transportation have developed different frameworks, referred to as Choice models. These frameworks relying on assumptions about the choice environment and the decision maker provide a mathematical representation to study choice behavior. The formulation of the choice model will vary based on the assumptions incorporated within the representation structure. These mathematical formulations are employed to analyze data from wide-ranging fields including economics, statistics, marketing, transportation, psephology, political science, and biostatistics.

In the transportation field, a large number of diverse examples of choice behavior is often encountered. At the individual level, the various choices situations encountered include: (1) travel mode choice—an individual chooses a transportation mode from a set of available transportation modes (such as car, bus, and walk), (2) route choice—a road user chooses a route from multiple alternatives for a trip (such as different Google Maps generated routes), (3) activity choice—an individual chooses an activity from a series of activities for the day (such as leisure and shopping), and (4) freight shipment size—an individual shipper determines the size of their shipment (such as under 50 pounds, 50–200 pounds and greater than 200 pounds). At the household level a sample of choices considered include (1) residential location choice—a household chooses a residential unit to buy or rent (spatial aggregated alternatives from the urban region such as traffic analysis zones or parcels), and (2) vehicle type choice—a household chooses to buy a vehicle defined by a combination of type (such as sedan minivan or coupe), make (such as Chevy, or Honda), and fuel type (electric or gasoline). At the firm level sample of choices evaluated include: (1) firm size and structure—a firm selects a size defined by the number of employees and hierarchy structure, and (2) firm location choice—a firm determines a location based on various incentives or tax implications. The examples illustrate the range and complexity of these choices.

In this article, we illustrate how choice or outcome models provide data supported analysis mechanisms for such choice contexts. The rest of the chapter is organized as follows: Section 2 summarizes mathematical frameworks commonly used for choice analysis in transportation. In Section 3, we provide a brief overview of case studies examining different choice contexts in transportation, Section 4 provides details of choice model application for travel mode share applications. Finally, Section 5 concludes the article.

Choice Model Architecture and Mathematical Formulations

Across the various choice contexts described earlier, DMs have to process the available information regarding the choice environment in arriving at their preferred choice. A DMs choice is dependent on how the DM defines the decision at hand, processes the alternatives (and their attributes) and the decision rule applied to arrive at the choice. The choice problem definition determines the potential alternatives of the choice problem. For example, if the DMs choice context is to determine the travel mode for an out of

home activity, the alternatives will possibly include all transportation modes (universal choice set of transportation modes) available in the study region. Of these alternatives, based on the DMs characteristics only a subset are feasible (feasible choice set). However, based on the attributes of the various alternatives it is possible that the decision maker will only consider a subset of alternatives from the feasible choice set (evoked choice set). The DM evaluates the alternatives in the evoked choice set based on the alternative attributes. For example, in travel mode choice context, alternative attributes include travel time and travel cost.

In choice contexts with smaller number of alternatives in the evoked choice set, DM can compare across alternatives using various decision rules to arrive at the final choice. In other cases, decision makers may consider a small subset of the alternatives to determine their choice. Earlier choice frameworks attempted a process of elimination (using satisfaction criteria [Murtaugh and Gladwin, 1980](#)) or ranking approach using lexicographic criteria ([Foerster, 1979](#)) to determine the DMs choice. However, these approaches might provide non-unique choices and/or choice outcomes that are impractical. Toward addressing these concerns, a scalar alternative utility-based approach was proposed. In this approach, each alternative is accorded a score based on a utility function (usually a linear additive function) of various alternative attributes. The alternative with the highest utility is considered to be the chosen alternative. Through the utility function, the approach allows for trade-offs (compensatory effects) between various attributes. For example, in a utility approach for travel mode choice, increase in travel cost can be compensated by improvements in travel time. While DMs are completely aware of the various attributes considered, analysts only observe the choice process partially. Hence, to allow for the influence of missing or unobserved information, utility is partitioned into two parts—observed component and unobserved component. The observed component accommodates for the impact of variables compiled in the data collection. The unobserved component takes the form of a stochastic error term to represent missing information. The alternative with the largest utility—computed as the sum of the two components—is considered the chosen alternative. Given the inherent stochasticity, the approach is referred to as the Random Utility Maximization (RUM) approach.

RUM choice models represent the most commonly employed frameworks for choice model development. The approach allows for the consideration of trade-offs across various attributes affecting the choice process. This implicit compensatory nature of the formulation allows for a poor performance on an attribute to be compensated by a positive performance on another attribute ([Chorus et al., 2008](#)). Several researchers, motivated by research in behavioral economics, have considered alternative decision rules for developing discrete choice models such as relative advantage maximization ([Leong and Hensher, 2015](#)), contextual concavity ([Kivetz et al., 2004](#)), fully-compensatory decision making ([Arentze and Timmermans, 2007](#); [Swait, 2001](#)), prospect theory (PT) ([Kahneman and Tversky, 2013](#); [Tversky and Kahneman, 1992](#)), and random regret minimization (RRM) ([Chorus, 2010](#); [Chorus et al., 2008](#)). Of these approaches RRM offers a framework that parallels RUM based models and is emerging as alternative modeling framework.

The reader would note that while all the choice examples presented in the introduction are discrete/categorical variables, some of them are potentially ordered discrete variables (for example number of employees) (Other examples of ordered discrete variables in the field of transportation include: (1) driver and passenger injury severity in traffic collisions, (2) household vehicle (automobile and bicycle) ownership, and (3) activity participation indicators (such as number of tours, number of stops, activity episode participation frequency, and activity duration)). The RUM and RRM approaches are applicable for analyzing all discrete variables. However, for modeling ordered dependent variables, another class of models referred to as ordered response frameworks also emerge as a potential model structure. In the following discussion, we present the mathematical details of the widely adopted frameworks organized by dependent variable characterization: (1) unordered dependent variable models and (2) ordered dependent variable models.

Unordered Dependent Variable Models

The unordered model frameworks are applicable for modeling all discrete choice or outcome dependent variables. In this section, we describe the RUM-based multinomial logit model and its extensions (mixed logit and latent segmentation based multinomial logit model) followed by a discussion of RRM-based multinomial logit model.

Multinomial Logit Model

Consider that a DM n has to choose an alternative i from a set of alternatives ($j = 1, 2, \dots, j$). With these notation, the utility in the RUM framework is defined as:

$$v_{ni} = \beta_i x_{ni} + \varepsilon_{ni} \quad (1)$$

where v_{ni} is the utility obtained by individual n by selecting alternative i from the choice set j . x_{ni} is the vector of alternative and DMs characteristics, β is a corresponding vector of parameters (including a constant) and ε_{ni} is the stochastic term that captures the unobserved part of the utility. The DM is expected to select an alternative that provides the highest utility. Given the inherent stochasticity involved, the choice of an alternative can only be arrived as the probability that a particular alternative (i in our case) provides the highest utility. The mathematical formula for an alternative probability of choice is affected by the assumptions about the stochastic term (ε_{ni}). Assuming ε_{ni} to be independent and identically Type I Standard Extreme Value distributed across the dataset simplifies the probability evaluation to the following multinomial logit form

$$P_{ni} = \frac{e^{v_{ni}}}{\sum_j e^{v_{nj}}} \quad (2)$$

Under different stochastic assumptions, such as ε_{ni} following a multivariate normal distribution would give rise to multinomial probit model.

The estimation of the parameters (β) is achieved by maximizing the likelihood function across the dataset, that is maximizing the probability of the chosen alternative across all records. The likelihood function for individual n is defined as

$$L_n = \sum_{\forall j} P_{nj}^{\gamma_{nj}} \quad (3)$$

where P_{nj} is the probability of the individual n choosing j and γ_{nj} is an indicator variable that takes the value 1 for chosen alternative, 0 otherwise.

The likelihood function for the entire data is computed as the product of likelihood over all the responses in the data as follows

$$L = \prod_{n=1}^N \sum_{\forall j} P_{nj}^{\gamma_{nj}} \quad (4)$$

For mathematical convenience, the natural logarithm of the likelihood function—log-likelihood—is maximized. The log-likelihood function takes the following form

$$LL = \sum_{n=1}^N \sum_{\forall j} \gamma_{nj} P_{nj} \quad (5)$$

The maximization of the function from Eq. (5) is achieved using different nonlinear optimization methods. With the increased access to computational resources, several proprietary and open-source software are available for estimating the models such as SPSS, SAS, ALOGIT, and R. The reader would note that the likelihood approach and software are similar for all models presented in the remaining discussion.

Mixed Logit Model

In the multinomial logit model, the vector of parameters estimated (β) is restricted to be the same across all DMs. The restriction is often referred to as the population homogeneity assumption. The mixed multinomial logit model accommodates for heterogeneity effects across DMs by allowing for the vector of parameters to follow a distribution across the dataset (as opposed to a fixed value). Based on the distributional assumption, the parameters that define the distribution are estimated.

In mixed logit models, the random utility formulation takes the following form (building on the formulation from Eq. (1)):

$$v_{ni} = (\beta_i + \eta_{ni})x_{ni} + \varepsilon_{ni} \quad (6)$$

where η_n is another column vector representing unobserved factors, usually considered to be independent realizations from a normal population distribution ($\eta_n \sim N(0, \sigma^2)$). Then, the probability that any DM will select alternative i for a given value of η can be expressed as:

$$P_{ni}|\eta = \frac{e^{[(\beta + \eta_{ni})x_{ni}]}}{\sum_{\forall j} e^{[(\beta + \eta_{ni})x_{nj}]}} \quad (7)$$

The unconditional probability then can be written as:

$$P_{ni} = \int_{\eta} (P_{ni}|\eta_{ni})dF(\eta_{ni}|\sigma) \quad (8)$$

where F is the multivariate cumulative normal distribution and is a vector of parameters. The integral in the probability expression cannot be evaluated using an analytical approach. Hence, the mixed logit model estimation is approximated using simulation methods for integral evaluations. The most commonly used method of simulation are Pseudo-Monte Carlo (PMC) simulation and Quasi-Monte Carlo (QMC) simulation (Bhat, 2003). The wide adoption of QMC approaches have resulted in ubiquitous adoption of mixed logit models for analysis in transportation and several other fields.

Latent Class Multinomial Logit Model

In the mixed logit model system, while the mean of the random coefficients can be allowed to vary across DMs based on observed variables, the approach usually restricts the variance and the distributional form of a random coefficient to be the same across all drivers. An alternative approach to relax the population heterogeneity assumption is the latent (or sometimes also referred to as endogenous) segmentation approach. In this approach, the DMs are allocated probabilistically to different segments, and segment-specific multinomial models are estimated. Such a segmentation approach is appealing in many respects: (1) each segment is allowed to be identified with a multivariate set of exogenous variables, (2) the probabilistic assignment of DMs to segments explicitly acknowledges the role played by unobserved factors in moderating the impact of observed exogenous variables, and (3) there is no need to specify a distributional assumption for the coefficients (Greene and Hensher, 2003; Yasmin et al., 2014).

Let us consider S homogenous segments of DMs (the optimal number of S is to be determined). We need to determine how to assign the DMs probabilistically to the segments for the segmentation model. The utility for assigning a DM n ($1, 2, \dots, N$) to segment s follows the multinomial logit structure as:

$$U_{ns} = \gamma_s z_n + \xi_{ns} \quad (9)$$

where z_n is a matrix of attributes that influences the propensity of belonging to segment s , γ_s is a vector of coefficients and ξ_{ns} is an idiosyncratic random error term assumed to be identically and independently Type 1 Extreme Value distributed across DMs n and segment s . Then the probability that DM n belongs to segment s is given as:

$$P_{ns} = \frac{\exp(\gamma_s z_n)}{\sum_s \exp(\gamma_s z_n)} \quad (10)$$

Within the latent segmentation approach, the probability of DM n choosing alternative i is given as:

$$P_{ni} = \sum_{s=1}^S (P_n(i)|s)(P_{ns}) \quad (11)$$

where $P_n(i)$ represents the multinomial logit probability for selecting alternative i within segment s following notation from Eq. (2).

Regret-based Multinomial Logit Model

The prevalent framework for developing discrete choice models is the RUM approach. RUM based approaches assume that decision makers prefer routes that provide the highest utility or satisfaction (Ben-Akiva et al., 1985; McFadden, 1974; Train, 2009). Among these approaches, the regret minimization approach offers a viable alternative approach due to its mathematical simplicity within a semi-compensatory decision framework.

The random regret associated with the choice of alternative i among j alternatives, each characterized by m attributes by the DM n is given as

$$RR_{ni} = \sum_{j \neq i} \sum_m \ln \{1 + \exp[\tau_m(x_{njm} - x_{nim})]\} \quad (12)$$

where τ_m denotes the estimable parameter associated with attribute x_m . x_{njm} and x_{nim} denote the values associated with attribute x_m for chosen alternative i and considered alternative j for DM n . In random regret models, the error term is assumed to be identically and independently Type 1 Extreme Value distributed across the dataset, which yields a closed form of probability expression similar to utility based multinomial logit model.

$$P_{ni} = \frac{e^{-RR_{ni}}}{\sum_{j \neq i} e^{-RR_{nj}}} \quad (13)$$

The model estimation follows a similar procedure of maximizing likelihood described earlier. Finally, the reader would note that similar extensions described in Sections 2.1.2 and 2.1.3 can be accommodated for RRM frameworks to relax population homogeneity assumptions.

Ordered Dependent Variable Models

The ordered response models represent the decision process under consideration using a single latent propensity. The choice probabilities are determined by partitioning the uni-dimensional propensity into as many categories as the dependent variable alternatives through a set of thresholds. The reader would note that the distributional assumptions of the unobserved component of the latent propensity determines the exact formulation of the model. The prevalent mechanism to analyze ordered discrete variables including ordered logit and generalized ordered logit models are presented in this section.

Ordered Logit Model

Let n ($n = 1, 2, \dots, N$) and j ($j = 1, 2, \dots, J$) be the indices to represent decision makers and alternatives, respectively. In the traditional OL model, alternative levels (y_n) are assumed to be associated with an underlying continuous latent variable (y_n^*). This latent variable is typically specified as the following linear function:

$$y_n^* = \alpha z_n + \varepsilon_n, \quad y_n = i, \quad \text{if } \tau_{i-1} < y_n^* < \tau_i \quad (14)$$

where y_n^* is the latent propensity for DM choosing an alternative level i , z_n is a vector of exogenous variables, α is a vector of coefficients to be estimated and ε_n is a random disturbance term assumed to be standard logistic. The latent propensity y_n^* is mapped to the observed ownership levels y_n by τ thresholds ($\tau_0 = -\infty, \tau_J = +\infty$) with the following ordering conditions:

$(-\infty < \tau_1 < \tau_2 < \dots < \tau_{j-1} < +\infty)$. Given these relationships across the different parameters, the resulting probability expression takes the following form:

$$P_{ni}(y_n = j) = \Lambda(\tau_n - \alpha x_n) - \Lambda(\tau_{j-1} - \alpha x_n) \quad (15)$$

where $\Lambda(\cdot)$ is the standard logistic cumulative distribution function (see [Greene and Hensher, 2010](#); [Train, 2009](#) for more details). A standard normal distributional assumption for ε_n would result in an ordered probit model system.

Generalized Ordered Logit Model

The generalized ordered response model relaxes the constant threshold across population restriction to provide a flexible form of the traditional OL model. The basic idea of the GOL is to represent the threshold parameters as a linear function of exogenous variables ([Eluru et al., 2008](#); [Maddala, 1983](#); [Srinivasan, 2002](#); [Terza, 1985](#)). Thus, the thresholds are expressed as:

$$\tau_{nj} = \text{function of } (Z_{nj}) \quad (16)$$

where Z_{nj} is a set of exogenous variable (including a constant) associated with j th threshold. Furthermore, to ensure the accepted ordering of observed discrete severity $(-\infty < \tau_{i,1} < \tau_{i,2} < \dots < \tau_{i,j-1} < +\infty)$. We employ the parametric form employed by ([Eluru et al., 2008](#)):

$$\tau_{nj} = \tau_{n,j-1} + \exp(\delta_{nj} Z_{nj}) \quad (17)$$

where δ_{nj} is a vector of parameters to be estimated. The remaining structure and probability expressions are similar to the OL model. For identification reasons, we need to either suppress the latent propensity of one of the δ_{nj} vectors. The model estimation follows a similar procedure of maximizing likelihood described earlier. Also, the reader would note that similar extensions described in Sections 2.1.2 and 2.1.3 can be accommodated for ordered response frameworks to relax population homogeneity assumptions.

Case Studies

To illustrate the diverse application of choice models in transportation, we present a brief summary of choice model application for different transportation empirical contexts (The reader would note that an exhaustive review of studies employing choice models is beyond the scope of the chapter). [Table 1](#) provides the summary of studies with information on study region, transportation topic of interest, data elicitation approach employed in the study, dependent variable used along with the details of the alternatives considered, choice model estimated, and the independent variables found to affect the choice process. Several observations can be made from the summary presented in [Table 1](#). First, choice models are applied for examining different transportation dimensions such as passenger and freight travel model choice, route choice, activity type choice, residential location choice, electric and autonomous vehicle purchase decisions, activity destination choice and comparison of travel times by mode. Second, the dependent variables vary considerably in terms of the number of alternatives ranging from 2 through 30. Third, the methodologies considered in these studies span the spectrum of choice models including simple binary logit models to panel mixed multinomial logit models. The studies also encompass RUM and RRM based models. Finally, a detailed summary of the independent variables considered for each study is included in the table. This summary on factors highlight how the adoption of these choice model frameworks can offer insights on a host of independent variables such as (1) DM's socio-economic and socio-demographics, (2) alternative specific characteristics such as mode characteristics, and dwelling unit characteristics, and (3) choice environment attributes such as transportation network infrastructure attributes, built environment factors, and regional and environmental factors.

Mode Share Models

In the transportation field, travel mode share models represent the most common application of choice models. Among choice models, the most commonly employed frameworks include unordered model systems such as RUM based multinomial logit and RUM based Mixed Logit. Recently RRM-based multinomial logit and mixed logit have also been applied. These model systems provide an understanding of the impact of various attributes affecting mode choice.

Traditionally, travel mode choice models are estimated using household travel survey data. In these surveys, individual travel diaries compile information on travel mode choice for every out of home travel episode. These travel episodes can be modeled individually as a trip or can be considered as a chain of trips in the form of trip chain or tour. Depending on the modal aggregation by trip or tour, the model developed will either represent a trip level mode choice or tour level mode choice. In all these models, the data compiled from the survey provides only a subset of information necessary for model estimation. To elaborate, the level of service information (such as travel time and cost by mode) is usually provided by respondents only for the chosen alternative. In the model estimation process, the analyst will need to build the other alternatives under consideration for the specific record (trip or tour) and then generate level of service measures for all these alternatives. The generation of level of service measures is likely to be challenging. For instance, the travel cost of a trip by public transit is not likely to be easy to estimate if the individual uses a monthly or annual pass. The analyst will need to estimate the number of potential instances the individual will use transit for in determining the record

(2019)	Japan	Autonomous vehicle	Survey	Ownership of autonomous vehicles	Mixed Logit	Alternative characteristics: Additional purchase cost, Insurance reduction rate, parking cost reduction, Choice environment attributes: release time of AVs to market, penetration rate of AVs, driving experience (short and long terms), age and income of the respondent.
Hasnat et al. (2019)	Central Florida Region, USA	Destination choice	Location based social media data	Destination choice among a choice set of 30 census tracts	Panel Latent Segmentation Multinomial Logit	Origin and destination characteristics: residential, industrial, recreational, office, agricultural, land use mix, per capita income, number of schools, hospitals and civic centers.
Faghih-Imani et al. (2017)	New York, USA	Bike share	New York City bike data	Faster mode of travel (bicycle or cab)	Panel Mixed Multinomial Logit	Distance between origin and destination Trip characteristics: Time of day, trip distance, whether the trip includes crossing a bridge or not Origin and destination attributes: Station capacity, length of cycling facilities, length of streets, number of restaurants, population density, employment density, presence of transit station.

level cost. Similar challenges exist in evaluating automobile record level travel costs as maintenance and operational costs vary substantially based on the vehicle used for travel as well as the frequency of use. Thus, in transportation, analysts typically use urban regional traffic analysis zone (TAZ) level travel time and travel cost matrices for analysis. These matrices are generated using traffic assignment results from regional travel demand models. To be sure, the approach does result in some conceptual challenges. For example, changes to travel mode preferences will modify the level of service matrices and vice versa. Hence, it is prudent to consider multiple iterations between mode choice and the traffic assignment process to ensure the level of service estimates used in mode choice are realistic.

The model estimation will consider several variables including level of service attributes, DM socio-demographic and socio-economic attributes, transportation infrastructure and built environment variables. The specification of mode choice models for level of service attributes is different from other discrete choice contexts. Usually, the coefficients for independent variables are estimated specific to each alternative. However, for level of service attributes, it is useful to consider a generic parameter across all alternatives. For example, the generic parameter ensures that level of service parameters for variables such as travel time and travel cost are same across all modes. Further, the presence of generic parameters allows us to evaluate the trade-off between various mode specific level of service attributes. The trade-off between travel time and cost, defined as the value of time (VOT) or willingness to pay (WTP) is generated using mode choice estimates. For RUM-based multinomial model system, the measure is defined as

$$VOT_{RUM} = \frac{\beta_{tt}}{\beta_{tc}} \quad (18)$$

where β_{tt} and β_{tc} are estimates of travel time and travel cost respectively from the RUM based multinomial logit model.

For RRM framework, the trade-offs are dependent on levels of attributes and generated as:

$$VOT_{RRM} = \frac{\sum_{j \neq i} -\beta_{tt} \left(1 + \frac{1}{\exp[\beta_{tt}(t_j - t_i)]} \right)}{\sum_{j \neq i} -\beta_{tc} \left(1 + \frac{1}{\exp[\beta_{tc}(c_j - c_i)]} \right)} \quad (19)$$

where β_{tt} and β_{tc} are estimates of travel time and travel cost respectively from the RRM based multinomial logit model, t_i and t_j represent the travel time attributes for the chosen route i and considered route j , respectively. c_i and c_j are represent the travel time attribute for the chosen route i and considered route j , respectively. To be sure, these value of time expressions will need to be appropriately modified for mixed logit and latent segmentation models.

Conclusion

The current chapter provides an overview of model frameworks employed to model Decision Maker choice behavior in the context of transportation. Given the wide range of choice outcomes examined in transportation, multiple choice models useful for analyzing unordered and ordered discrete variables are presented. The unordered frameworks described include random utility-based multinomial logit model and random regret based multinomial logit model, and their mixed and latent segmentation variants. For ordered discrete variables, we present the traditional ordered model and its generalized variant. A brief overview of case studies covering a diverse set of choice contexts is also presented. The description of choice models was restricted due to space constraints. Several advanced modeling approaches (such as panel models, generalized extreme value extensions of traditional models) that build on the frameworks described in the chapter are developed in recent years in economics and transportation fields.

Introduction

Transportation infrastructure projects (hereon, projects) are primarily meant for mitigating existing transportation problems such as traffic congestion, or to improve accessibility, mobility, or connectivity in terms of routes or modes of transport. However, there are several concerns, such as safety, equity, environmental sustainability, and availability of funds that determine the selection of a particular project for implementation. In addition, there are other considerations, such as short- and long-term economic growth and job creation resulting from the completion of the project. Not only that some of these objectives conflict or compete with each other, but the value of project alternatives perceived by different stakeholders based on the stated objectives could also be vastly different. Exclusion of important objectives could lead to wrong choice of alternatives, resulting in unanticipated project overruns due to political and legal hurdles. Foreseeing these issues, legislation often mandates that several project alternatives must be explored before a project's implementation and a holistic analysis must be carried out with due consideration to the concerns of stakeholders and the public in general. The challenge for the agencies is to identify and apply appropriate methods to select the alternatives that deviate the least from the stated project objectives and concerns of the stakeholders. Multiple criteria decision analysis (abbreviated as MCDA; also known as multiple criteria decision-making) methods are increasingly becoming popular tools for transportation-related project selection due to their ability in handling competing and conflicting interests of various stakeholders.

MCDA techniques are a set of decision-support tools available to transportation agencies to evaluate, assess, and rank project alternatives based on a multitude of relevant stakeholder concerns (Kiker et al., 2005). The concerns, in a formal decision-making problem setting, are otherwise called "criteria." In general, MCDA methods break down a complex decision-making problem (project selection) into several subproblems, analyze each of the available alternatives based on the subproblem, and then integrate the findings to choose the best alternative among the available options for implementation. MCDA also provides a systematic and transparent procedure for evaluating alternatives with due consideration to all concerns and perspectives, however, insignificant in scope they may be.

The key advantage of MCDA methods is that they are capable of incorporating subjective information. In this way, MCDA methods can consider both tangible and intangible benefits and costs of project alternatives leading to more meaningful decisions

supported by sound rationale. The two aspects that make different MCDA methods distinct are (1) the methods by which weights for preferences of stakeholders are assigned; and (2) the way in which uncertainties in subjective preferences are handled. The main focus of this article is to outline the general framework of MCDA and introduce some of the widely adopted MCDA techniques used for addressing transportation-related decision-making problems.

Stages in Multi-Criteria Decision Analysis

Any MCDA involving multiple stakeholders can be divided into eight major stages ([Department of Communities and Local Government, 2009](#)). In the rest of the section, each of these stages is discussed in detail.

Delineate Scope of the Decision-Making Problem (Project)

This stage involves establishing the basic setting for the MCDA problem to be solved. Specifically, four aspects of the problem are defined: (1) the aims of the project; (2) participants (decision-makers and key players concerned with the project); (3) the socio-technical apparatus of the MCDA; and (4) the context of the MCDA. The aims of the MCDA are broad intentions that the agency (which is responsible for the project) desires to achieve by the implementation of the projects. The next step involves identifying the decision-makers and key players (MCDA participants) who can contribute to the assessment of various perspectives and concerns related to the project during the MCDA process. The MCDA participants must be able to bring in the concerns of all stakeholders who could be directly or indirectly affected as well as the opinions of the subject matter experts who have adequate knowledge in the domains pertinent to the project. In the third step, the methods and time frame for collecting relevant information from the participants are decided. Facilitated workshops and surveys are widely adopted methods for collecting stakeholder inputs. In addition, the various MCDA techniques appropriate for the current decision-making problem must be identified and the corresponding advantages and limitations must be ascertained. In the last step, the resources for the MCDA are allocated appropriately. External factors such as political, economic, social, and technological systems that could influence the project may also be considered so that further fine-tuning of the setup could be done before the commencement of the MCDA.

Identify the Project Alternatives

For a project to be implemented, several alternatives may exist that can achieve the stated aims and objectives; however, resource constraints make implementation of only one or a few of the alternatives viable. While some projects may have predefined alternatives, in some others, the MCDA must develop alternatives in consultation with the key players and stakeholders. Along with new alternatives, “do-nothing” must also be considered; in many cases, continuing the status quo may have more value over all other alternatives. The development of alternatives may be done in several steps, as appraising the short-term and long-term implications of alternatives could motivate the stakeholders to come up with better alternatives. Flexibility in modifying the initial pool of alternatives is therefore key in a successful MCDA endeavor.

Define Criteria for Evaluating Alternatives

A criterion, in MCDA context, is defined as “an individual measurable indicator of a key value dimension” ([Department of Communities and Local Government, 2009](#)) or “a particular perspective according to which alternative technologies may be compared” ([Belton and Stewart, 2002](#)). The broader objectives of the project are achieved by ensuring desired level of the selected criteria. The criteria evaluate the value and the consequences (both positive and negative) of the project alternatives, leading to the selection of the best alternative. Criteria can be either quantitative or qualitative in nature based on their measurability. The criteria must reflect the undertaking agency’s stated values and goals, the specific objectives of the project, and the concerns of the participants and the general public. Once the criteria are identified, a systematic representation of the objectives and criteria is developed depending on the complexity of the problem ([Fig. 1](#)).

In complex MCDA problems involving multiple levels of objectives, a value tree is used. A value tree refers to organizing criteria by clustering them under respective higher- and lower-level objectives of the project. This representation facilitates the evaluation of alternatives in terms of various objectives and sub-objectives. In a value tree, the top-level objectives are the costs and benefits of the project, under which other lower-level objectives are clustered. In the case of simple MCDA problems, a simple performance matrix is appropriate for representing alternative-criterion relations.

Assess the Performance of Alternatives

The next step in MCDA is to assess the various alternatives based on the final set of criteria. MCDA techniques use preference scores to normalize various qualitative and quantitative performance measures for comparison across criteria. The preference scores are articulated during workshops and surveys. The alternatives are assigned with a score based on a relative scale in which a low score refers to a low level of preference and a high score indicates high level of preference of a particular alternative. Preference scores indicate the relative strength of preference of one alternative to others for each of the criteria. The preference scores obtained must be

Alternatives	Criterion 1 (Objective 1)	Criterion 2 (Objective 2)	Criterion 3 (Objective 3)
Alternative 1			
Alternative 2			
Alternative 3			
Alternative 4			

(B) Performance matrix

Figure 1 Formats of value tree and performance matrix.

checked for consistency as part of input validation. Ensuring consistency of the scores within and across criteria is crucial and requires several iterations of preference score assessments until the scores are agreed upon by all the key players and stakeholders.

Assign Weights for Different Criteria

While preference scores are effective in comparing alternatives based on a particular criterion, it requires further processing for cross-criterion comparisons. After all, the goal of MCDA is to aggregate the preferences based on various criteria to assign overall scores for alternatives. Weights are assigned to each criterion to denote their (criteria) relative importance. Consequently, the “weighted” preference scores can be combined so that the final score would reflect not only the relative preference of alternatives based on the criteria, but also their importance in achieving the project objectives.

Calculate the Overall Score of Alternatives

Once the weights are derived, the overall weighted preference scores at each level in the value tree are calculated as follows:

$$S_i = \sum_{j=1}^n w_j s_{ij}$$

where S_i is the overall score corresponding to alternative i , w_i is the derived weight for criteria j , and s_{ij} is the preference score corresponding to criteria j and alternative i . One key issue often encountered in this stage is the presence of dependence among some of the criteria. The preference of an alternative may be dependent on the preference of another criteria, leading to unreasonable scores for alternatives. However, there are several alternative mathematical techniques available to deal with such situations.

Analyze the Results and Make Recommendations

The top-level weighted scores of alternatives can be used to rank them based on the order of suitability for the project objectives. In addition, cross-alternative comparisons can also be carried out based on the scores at each level of the hierarchical clustering of objectives. In the case of unexpected results from the ranking exercise that are contrary to the intuition of the participants, further

Table 1 Major classifications of multi-criteria decision-making techniques

<i>Classification basis</i>	<i>Categories</i>	<i>Unique characteristics</i>	<i>Example techniques</i>
Selection of alternatives (Triantaphyllou, 2013)	Multi-objective decision-making (MODM)	Alternatives are not predefined, and criteria are expressed in continuous form	Weighted global criterion method, goal programming
	Multi-attribute decision-making (MADM)	Alternatives are predefined and discrete in nature	Analytical hierarchical process, technique for order preference by similarity
Range of application (Belton and Stewart, 2002)	Value measurement methods	Numerical measures for representing preference of one alternative over another	Analytical hierarchical process, weighted sum method
	Goal, aspiration, or reference-level methods	Acceptable level of a criterion is predefined	Goal programming, technique for order preference by similarity
	Outranking methods	Pairwise comparison of alternatives and aggregation of results across criteria	Elimination of choice expressing reality, preference ranking, organization method for enrichment evaluation methods
Level of aggregation of alternatives (Mardani et al., 2015)	Complete aggregation	Comparison of all alternatives in a single step	Technique for order preference by similarity
	Partial aggregation	Pairwise comparison of alternatives	Analytical network process, analytical hierarchical process

formal discussions must be organized to review the results and their implications following implementation. Stakeholder discussions on the MCDA results may open up new possibilities in terms of alternatives or may be helpful in identifying the pitfalls in the decision-making process.

Sensitivity Analysis and Final Selection of Alternative

Sensitivity analysis provides insights into the implications resulting from any uncertainty in the information articulated from the participants of the MCDA. The final scores may be highly sensitive to some of the subjective inputs and MCDA method used. Sensitivity analysis is capable of pinpointing the root causes of uncertainties in implications of project alternatives, may be due to poorly defined criteria weights or uncertain model inputs (Saltelli et al., 1999).

Classifications of MCDA Techniques

Several classifications exist for categorizing MCDA methods. The most important among these are with respect to selection of alternatives range of application and level of aggregation of alternatives, as presented in Table 1.

Commonly Used MCDA Techniques for Transportation-Related Decision-Making

The following are some of the major MCDA techniques that are used for transportation-related decision-making involving multiple stakeholders and project objectives.

Weighted Global Criterion Method

The weighted global criterion method is a multi-objective decision-making framework in which the utility functions corresponding to the various objectives of the project are combined into a single global function. The alternatives are generally not predefined and the criteria are represented using a continuous hypercube. The utility functions are constructed such that the global function minimizes the distance between the solution point and the “utopia point.” The utopia point refers to the most-desirable (ideal) solution that may or may not lie within the criterion space. While several weighted utility functions exist, the following are the most-widely adopted ones.

$$U = \left\{ \sum_{i=1}^k w_i^p [F_i(\mathbf{x}) - F_i^0] p \right\}^{\frac{1}{p}}$$

$$U = \left\{ \sum_{i=1}^k w_i^p [F_i(x) - F_i^0] p \right\}^{\frac{1}{p}}$$

where $w_i \in \mathbf{w}$ is the weights corresponding to each of the project objective i such that $\sum_{i=1}^k w_i = 1$ and $w_i > 0 \forall i$, $\mathbf{x}$ is the set of criteria, $F_i(\cdot)$ is the function that defines the objective i , F_i^0 is the ideal value of the objective i , and $p = 1, 2, 3, \dots$

The weights are directly proportional to the importance of each of the project objectives. The method is commonly employed in resource allocation problems.

Goal Programming

Goal programming, first introduced by Charnes et al. (1955), is a commonly used multi-objective decision-making technique to find a project alternative which is "acceptable" for all the key players and stakeholders. This is a type of global criterion method in which the absolute deviation from ideal solution points corresponding to each of the objectives are minimized as follows:

$$\begin{aligned} \min \quad & \sum_{i=1}^k (d_i^+ + d_i^-) \\ \text{s.t.} \quad & F_i(\mathbf{x}) - d_i^+ + d_i^- = b_i, \quad i = 1, 2, 3, \dots, k \\ & d_i^+, d_i^- \geq 0, \quad i = 1, 2, 3, \dots, k \\ & d_i^+ d_i^- = 0, \quad i = 1, 2, 3, \dots, k \end{aligned}$$

where b_i is the desired goal corresponding to project objective i , $\mathbf{x}$ is the set of alternatives, $F_i(\mathbf{x})$ is the utility function corresponding to objective i , and d_i^+ and d_i^- represent the overachievement and underachievement of j . There are three types of goal programming formulations based on how the bounds of goals are defined, namely, lower one-sided goal, upper one-sided goal, and two-sided goal.

The extension of goal programming with differential weights assigned to goal functions based on their relative importance is called Archimedean goal programming. While goal programming can be effective in obtaining a solution acceptable to the key players and stakeholders, there is no assurance that the solution is Pareto optimal. Another major limitation is that computation becomes complex if there are additional variables and nonlinear equality constraints in the optimization problem.

Weighted Sum Model

Weighted sum model is the simplest multi-criteria decision-making method introduced by Fishburn (1967) in which the utility functions of various project objectives are weighted according to their importance and are summed up as follows:

$$A_i^{\text{WSM_score}} = \sum_j^n w_j a_{ij}, i = 1, 2, \dots, m, j = 1, 2, \dots, n$$

where $A_i^{\text{WSM_score}}$ is the weighted score for alternative i , w_j is the weight corresponding to objective j , and a_{ij} is the performance value of i corresponding to j . The performance values must be depicted in the same unit across criteria. The alternative that has the maximum weighted score is the most preferred one. In the case of multi-objective decision-making problems, the solution point can be obtained by maximizing the weighted sum of utility functions.

$$U = \sum_j^n w_j F_j(\mathbf{x}), j = 1, 2, \dots, n$$

The weights in the weighted sum model formulation are nonarbitrary and must be derived using methods such as ranking methods, rating methods, paired comparison methods, etc. In addition, the criteria selected must also be independent of each other to ensure that the scores are not amplified by the presence of correlated criteria.

Analytical Hierarchical Process (AHP)

Analytical hierarchical process (AHP), introduced by Saaty (1990), has been an effective tool for multi-criteria decision-making problems involving ranking, selection, evaluation, optimization, and prediction. AHP involves four major steps. In the first step, the decision-making problem is structured in the form of a value tree, where the top level denotes the goal of the project, followed by the objectives and sub-objectives in intermediate levels and the corresponding criteria take up the bottom layer (Fig. 1A). In the second step, pairwise comparison of criteria is carried out by taking one pair at a time and obtaining the ratio of importance of one criterion over another from the participants. The ratios are later arranged in a comparison matrix. Usually, a scale ranging from 1 to 9 is used, where the score 1 denotes a situation where the criteria are equally important and a score of 9 denotes that the first in the pair is extremely important over the second. The intermediate values refer to intermediate preference states. Reciprocal of the scores is used if the second element is more preferred over the first. The consistency of the articulated comparison matrix is checked by finding the consistency ratio (CR), which is a function of the consistency index (CI) of the matrix (the principal eigenvalue of the matrix) and the random consistency index (RI). If the consistency ratio is not near to the ideal value of zero (less than 10%), the articulation may be repeated until desired level of consistency is achieved. Then, the weights of the criteria are obtained by calculating the normalized principal eigenvector corresponding to the highest eigenvalue of the comparison matrix.

Figure 2 Structure of an analytical network process problem.

In the third step, a similar procedure as in the previous step is implemented to obtain the priorities based on each of the criteria. The comparison matrix denotes the preference of each alternative over other corresponding to a specific criterion. If several levels of objectives and sub-objectives are to be dealt with, a bottom-up approach must be followed for pairwise comparison of alternatives. The normalized principal eigenvector corresponding to each of the comparison matrices in this step reflect the preference of various alternatives with regard to a specific criteria. In the final step, the priority vectors of both criteria and alternatives are appropriately combined to obtain the composite scores of each alternative indicating their strength of preference.

Analytical Network Process (ANP)

Analytical network process (ANP) is a generalized version of AHP where the decision-making problem is structured as a network (Fig. 2) and not as a hierarchy of goal, objectives, and criteria (Saaty and Vargas, 2013). This method is appropriate when dependencies exist among decision criteria. The dependencies and feedback loops represented by the network can compute the criteria weights more precisely, eliminating any overestimation of influence of a criterion. ANP involves four major steps.

In the first step, the network consisting of the goal cluster (node G), criteria nodes (nodes $C_1, C_2, \dots, C_n$) and alternatives cluster (nodes $A_1, A_2, \dots, A_m$) along with the dependencies and feedback links. The criteria are clustered according to the objectives. In the next step, the weights of nodes are obtained by implementing second and third steps described in AHP. Four types of pairwise comparisons are done in this step to obtain the unweighted super matrix of the network comparison of criteria with goal, comparison among criteria, comparison of alternatives with respect to each goal, and comparison of criteria in each cluster with respect to each alternative. In the third step, the unweighted super matrix is converted into weighted super matrix. For this purpose, three types of cluster-level pairwise comparisons are carried out—comparison of criteria clusters with respect to goal, comparison of all criteria and alternatives clusters with respect to each of the criteria clusters, and comparison of criteria clusters with respect to each of the alternative clusters. In the final step, the weighted super matrix is multiplied to itself until all the columns become equal. The column values in the limiting matrix represent the weights of the criteria and the alternatives.

Preference Ranking Organization Method for Enrichment Evaluation (PROMETHEE) Methods

PROMETHEE methods also use pairwise comparisons between alternatives to sort them in the order of preference based on a finite number of criteria (Brans and Vincke, 1985). The methods are implemented in three steps. In the first step, such as AHP and ANP, alternatives are compared in pairs for each of the criterion. However, a preference scale (ranging from 0 representing no preference or

indifference to 1 representing strict preference) is used for representing the preference of one alternative over the other in each pair. A generalized criterion function is used to convert the preference of the decision-maker into a preference score. In the next step, for each pair of alternative a and b , a multi-criteria preference index $\Pi(a, b)$ is computed as the weighted average of preference scores corresponding to the criteria to represent the relative overall preference of alternatives in each pair. In the final step, the leaving flow $\phi^+(a)$ and the entering flow $\phi^-(a)$ for each of the m alternatives are calculated as follows.

$$\phi^+(a) = \frac{1}{m-1} \sum_{i=1, i \neq a}^m \Pi(a, i)$$

$$\phi^-(a) = \frac{1}{m-1} \sum_{i=1, i \neq a}^m \Pi(i, a)$$

The leaving flow value indicates the extent of preference of a over other alternatives, whereas the entering flow represents the extent of preference of all other alternatives over a . The various methods within the family of PROMETHEE methods differ in how alternatives are sorted based on the leaving flow and entering flow values. For example, in PROMETHEE I, a is preferred over β if $\phi^+(a) \geq \phi^+(b)$ and $\phi^-(a) < \phi^-(b)$. In the case of PROMETHEE II, the net flow ($\phi^+(a) - \phi^-(a)$) is used to develop a complete ranking of alternatives in one single step.

Elimination of Choice Expressing Reality (ELECTRE)

ELECTRE methods use the concepts of concordance and discordance (non-concordance) to develop outranking relations among the project alternatives (Figueira et al., 2005). Three levels of outranking relations are used—strictly preferred, indifferent, and incomparable. The ELECTRE methods essentially have two steps, namely aggregation and exploitation. In aggregation phase, overall preference of one alternative over another is computed using pairwise outranking assertions. For an alternative a to be strictly preferred over b , both concordance and discordance conditions must be satisfied. The concordance condition for the assertion that a is strictly preferred over b (aSb) is satisfied if a majority of such outranking relations between a and b follows the same assertion. The discordance condition is satisfied if none of the criteria in the minority subset shall strictly oppose the assertion aSb . The outranking relations can be crispy, fuzzy, or embedded in nature. In the exploitation phase, a small set of alternatives is selected based on the outranking relations among alternatives. Several methods, such as graph kernel method, are used for this purpose.

ELECTRE methods are broadly classified into choice problematic, ranking problematic, and sorting problematic, based on the nature of the decision-making problem.

Technique for Order Preference by Similarity (TOPSIS)

TOPSIS is a multi-attribute decision-making method that checks for similarity of each alternative to the ideal solution to rank the alternatives in the order of preference (Tzeng et al., 2011). The best alternative is the one which is the nearest to the positive ideal solution and the farthest from the negative ideal solution. The positive ideal solution is the one that maximizes the benefit criteria and minimizes the cost criteria. On the other hand, the negative ideal solution is the one that minimizes the benefit criteria and maximizes the cost criteria. TOPSIS has essentially three steps for implementation. In the first step, the normalized weighted preference matrix is obtained by multiplying the elements in the normalized preference matrix with the corresponding criteria weights. In the second step, the positive and negative ideal solutions are computed. As the names suggest, the positive ideal solution is calculated using the best possible values for the criteria and the negative ideal solution is obtained using the worst possible values for the criteria. In the last step, the distance from each of the project alternatives to the positive and negative ideal solutions is computed using Euclidean distance. The relative closeness index for each alternative, computed as the ratio of the distance to the negative ideal solution to the sum of positive and negative ideal solutions, is used to identify the best alternative.

Summary

In this article, a brief introduction to the concept of MCDA is provided and some of the popular techniques used for MCDA are discussed. MCDA methods are appropriate for transportation-related project prioritization, when consideration of opinions, concerns, and demands of a diverse group of stakeholders become integral to the decision-making process. While only a very few MCDA techniques are introduced, there are several other techniques which may become equally handy while dealing with MCDA problems. In many past studies, application of hybrid MCDA methods (combination of two or more methods) has also been investigated. Nevertheless, the aim of any MCDA technique remains the same—choose a desired number of project alternatives from a large pool which are least deviating from the expectations of the stakeholders and key players.

While MCDA has numerous advantages over conventional decision-making systems, there are several major challenges as well. MCDA methods could produce misleading results in some cases, as they are vulnerable to personal biases in preferences. In addition, the selection of MCDA method is very crucial and depends on the problem under consideration, as different methods have different

approaches for deriving criteria weights and alternative selection. Some of the aspects that must be considered while choosing MCDA techniques are enlisted as follows (Bonissone, 2008).

1. Uncertainty and imprecision in the subjective preferences of the MCDA participants and the ability of the MCDA methods to handle them.
2. High dimensionality of criteria space (more number of criteria makes preference articulation complex).
3. Ability to identify inconsistencies in stakeholder preferences and the flexibility of MCDA methods update them.
4. Ease of development, deployment, and management of adaptive and distributed decision support systems using the MCDA methods.

In addition, transportation projects have huge impact on the society and regional economy and therefore adequate attention must also be given to the uncertainties in implications of the alternatives selected by the MCDA procedures. Because of these reasons, the decision-makers must be aware of the merits and demerits of the MCDA approaches available before undertaking the analysis.

Overview

Title 23, United States Code, Section 502 authorizes the US Department of Transportation (USDOT) to carry out transportation research to measure the performance of the surface transportation systems in the United States, including the efficiency, energy use, air quality, congestion, and safety of the highway and intermodal transportation systems. The USDOT has overall responsibility to obtain current information on national patterns of travel, establish a database to better understand travel behavior, evaluate the use of transportation facilities, and gauge the impact of the USDOT's policies and programs.

The Federal Highway Administration (FHWA) Office of Policy Information sponsors the National Household Travel Survey (NHTS, previously called the Nationwide Personal Travel Survey) to collect information on the travel of US residents. The survey has been conducted periodically since 1969 and has evolved in methods and uses across the decades. The 2017 NHTS, the most recent data released in April 2018, contains information for 264,000 completed responses from people aged 5 and older in 130,000 households (Fig. 1). Every household member recorded their travel for a single, assigned travel day (adults proxied for children 13 and under). This allows the analysis of the interactions between household members and the linking of travel to the individual and household characteristics, such as income, number of vehicles, and the presence of children. The findings of the survey are documented in the Summary of Travel Trends, which is available at <https://nhts.ornl.gov/>.

Uses of the Data

Data from the NHTS are widely used to support research needs within the USDOT, and state and local agencies, in addition to responding to queries from Congress, the research community, and the media on important issues for transportation policy and planning. A compendium of uses of the most recent NHTS data (compiled by Oakridge National Laboratories for the 2018 calendar year) is shown in Fig. 2.

Within the USDOT, the FHWA holds responsibility for technical and funding coordination and is a primary user of the data. Other primary data users include the National Highway Traffic Safety Administration (NHTSA), Federal Transit Administration (FTA), and the Bureau of Transportation Statistics (BTS); these agencies have historically participated in project planning and financial support. For example, NHTS data are integral to the calculation of the model year Corporate Average Fuel Economy (CAFE) standards, which are regulations issued by the National Highway Traffic Safety Administration (Chajka-Cadin et al., 2017). The data are commonly used to estimate vehicle miles of travel by specific groups, such as age groups or men and women drivers (Claude Ouimet et al., 2010), and the Bureau of Transportation includes analysis of personal travel from the NHTS data in the Transportation Statistics Annual Report (USDOT BTS) (US Department of Transportation, 2019).

The NHTS informs other policy research, especially energy consumption. For example, the Energy Information Administration (EIA) uses the NHTS data as a source of information on household fuel consumption for transportation (USDOE EIA) (US DOE Energy Information Agency, 2015) and the Environmental Protection Agency (EPA) to provide default values for the Moves2010 model (Beardsley, 2011) and to estimate the value of various policy initiatives related to fuel consumption and greenhouse gas emissions (US DOI EPA) (Department of Interior Environmental Protection Agency Green Vehicle Guide, 2015).

Travel behavior studies are a common use of the data, for instance analysis related to the impact of transportation policies on various population groups. Some of these studies are related to social equity (Sanchez et al., 2003), gendered travel (Hsu and Saphores, 2013), or have a focus on tracking age cohorts—like baby boomers (McGuckin and Lynot, 2012) or millennials (Dutzik et al., 2014). And the NHTS is used for pedestrian studies, including by the Safe Routes to School National Partnership (Randolph, 2015). A relatively new area of use is to assess the way that active transportation can improve public health: the Centers for Disease Control (CDC, 2010a) uses the data on the percent of children who walk to school (among other indicators) from the NHTS as part of their Healthy People 2020 (CDC, 2010b).

Figure 2 Compendium of uses of the National Household Travel Survey. *Source: USDOT FHWA National Household Travel Survey compendium of uses. Available from: <https://nhts.ornl.gov/compendium>.*

Advocacy groups and nonprofit organizations are another set of data users. For example, the American Association of Retired People (AARP) and the American Association of Automobiles Foundation for Traffic Safety (AAAFTS) often use NHTS data in their reports and presentations to increase awareness about priority topics and to lobby Congress for action. And, finally, transportation modelers use the NHTS data to provide context for regional and metro-area level travel behavior. Overall, policymakers, transportation planners and modelers, and decision-makers use the data and statistics generated from the NHTS extensively to understand the travel of the American public.

Biography

Nancy McGuckin is a senior advisor and consultant to federal, state, and local public agencies and private clients. She conducts primary research, data mining, and insightful statistical analysis to interpret and forecast travel behavior, examine special populations and equity issues, and help develop robust performance measures on these and other policy initiatives. She is well known for her work identifying technological, demographic, and cultural impacts on travel behavior, her rigorous data analysis, and her ability to communicate complex issues in a clear and concise manner.

Social, technological, and economic dynamics have all significantly affected travel rates—sometimes in surprising ways. Ms. McGuckin offers new insights gleaned from data mining the 40 years of NHTS, Census iPUIMS, and ACS/Journey-to-Work data to develop a context for understanding the recent unprecedented shifts in travel. For example, she has recently completed the NHTS 2017 Summary of Travel Trends (starting with the 1969 data, available from: https://nhts.ornl.gov/assets/2017_nhts_summary_travel_trends.pdf) and was a major contributor to the Transportation Statistics Annual Report (a summary of data findings important to policy makers, available from: <https://www.bts.gov/sites/bts.dot.gov/files/docs/browse-statistical-products-and-data/transportation-statistics-annual-reports/TSAR-2018-Web-Final.pdf>).

As part of her efforts to reinforce evidence-based policies, she frequently develops and posts briefs and presentations on critical issues related to travel behavior, demographic trends, and other topics at: www.travelbehavior.us.

Introduction

People make different choices because their preferences are different. This is true in many contexts, including transportation. Understanding and predicting traveler behavior is therefore crucial in order to design and operate transport systems that meet heterogeneous demand while minimizing effects negative to the environment as well as inefficiencies, such as congestion.

This article is devoted to route choice analysis and network modeling of heterogeneous traveler behavior. More precisely, we focus on analyzing and predicting path choice behavior with disaggregate stochastic models — discrete choice models — whose parameters are estimated using observed path choices (revealed preference data). The models are essentially used for two purposes. First, the interpretation of travel behavior by analyzing the parameter estimates. Such interpretations can for example be used as inputs in cost-benefit analysis of infrastructure investments. Second, predicting network traffic flows. Given an aggregate demand — number of people/vehicles traveling between each origin–destination (OD) pair — a disaggregate stochastic model distributes this demand over paths in the network. In this article we focus on disaggregate demand models and take aggregate demand as given and known. Of particular interest for flow prediction is the analysis of network changes. That is, the predictions should not only be accurate for the same network structure as during the data collection, but also generalize to new structures. This is why structural prediction models are used with attributes that aim to characterize the network, for example, type of infrastructure, travel times, and traffic signaling.

This article provides an overview of two, fundamentally different, modeling approaches to route choice analysis. We refer to them as path-based and arc-based and devote the third section to an overview of them. The purpose of this article is not to provide a detailed review of all types of path and arc-based models, rather we focus on advantages and drawbacks of the different modeling approaches from the perspective of the ultimate use of the models: behavioral interpretation, prediction, scenario analysis, or network design problems (i.e., optimization). To do so we provide a high-level description of related problems in the fourth section followed by the fifth section entirely devoted to the discussion of advantages and drawbacks of arc-based versus path-based models. Finally, Section 6 concludes.

Models for Analyzing and Predicting Path Choice Behavior

The problem of predicting how an aggregate OD demand distributes over paths in a network is a statistical learning problem. Having collected observations of individuals' trajectories in the network, the modeler's goal is to formulate a model, which identifies patterns in the data in order to accurately predict actual behavior. Nevertheless, modeling path choice should be driven not only by data but also by assumptions regarding how we expect individuals to behave. In the case of path choice in a transportation network, it is plausible to assume that decisions are not random but driven by a rational intent from individuals to minimize to some extent the disutility of traveling. Therefore path choice modeling can be cast as a problem of learning a utility function explaining a decision maker's behavior. In this section, we present different models to learn such a utility function and hence predict path choice behavior.

Preliminaries

We consider an oriented graph $G = (\mathcal{V}, \mathcal{A})$, where $\mathcal{V}$ is the set of vertices and $\mathcal{A}$ is the set of arcs. Arcs $a \in \mathcal{A}$ are characterized by a head node i_a and a tail node j_a , and are associated to a utility v_a . A path in the graph G is a sequence of arcs such that the head node of each arc is the tail node of the next. Deterministic attributes, such as travel time, road, and traffic signaling information, are associated with arcs and nodes in the network. In this article we do not cover the more complex case of stochastic attributes that has been studied, for example, in [Gao et al. \(2010\)](#).

Such graphs may serve as representations for all kinds of urban transportation networks, where nodes include origins and destinations, and a path represents at some level of detail an alternative to travel between an OD pair. Typically, a sequence of arcs could define a precise itinerary in a physical network, where nodes $v \in \mathcal{V}$ represent intersections between road segments. More generally, paths may also represent traveling alternatives in space and time. For instance, a multimodal trip composed of several legs, each consisting of a distinct transport mode, intermediate OD, and departure/arrival time, could be represented as a path in a time-expanded network. In such a graph, a node v represents a point in space and time, while arcs a define more generally a means to connect two nodes with a specific transportation service.

Deterministic Versus Stochastic Models

Distinct assumptions regarding user behavior lead to either deterministic or stochastic models to distribute the aggregate demand over paths. The simplest path choice model in the literature is in fact a deterministic shortest path algorithm, which assigns individuals to the shortest (i.e., maximum utility) path between each OD pair. However, using this model to predict route choice in practice would rely on very strong behavioral assumptions, which are rarely valid. Implied is that individuals all perceive the same path utilities, have perfect discriminatory power, and are able to select the single best path 100% of the time. In reality, we observe on the contrary that individuals behave heterogeneously for several reasons, such as distinct preferences or varying perception of path attributes.

A way to relax this strong behavioral assumption is to resort to *stochastic* path choice models. The hypothesis underlying such models is that travelers are random utility maximizers: each individual perceives his/her own utility, which may be based on personal preferences or criteria unavailable to the modeler. Hence the modeler does not know each individual utility, but only the distribution among the population. This leads to representing path utilities as random variables (consisting of a deterministic and a random term) and distributing the aggregate demand on the network's paths according to the probability of each path being optimal, that is, the one with maximum utility.

Whether a deterministic or stochastic model is used, in practice we *do not know* the utilities of the network's paths nor their distributions. However, observed trajectories relay information regarding what paths are used in the network. This is why path choice modeling is in fact an inverse problem, which consists in identifying from the data the true utility function within the path choice model under consideration.

This inverse problem can be approached in two ways. On the one hand, under the assumption of deterministic path utilities, the learning problem is simply an inverse shortest path, that is, identifying the values associated to each arc, which make observed paths optimal (see e.g., [Burton and Toint, 1992](#)). This problem is considered to be difficult because it is under determined. In other words, there does not necessarily exist unique arc utilities ensuring that observed paths are optimal. On the other hand, when assuming that utilities are random variables, the inverse problem becomes one of learning the parameters of a probability distribution over a set of paths. Observations can be interpreted as noisy, that is, deviating randomly from deterministic shortest paths according to the probability function. Inverse problems with noisy data pose a double challenge. The difficulty stems not only from nonuniqueness, but also from the fact that there may not be any nontrivial value of arc utilities, which accounts for observed behavior. For more information on such inverse problems, the reader is referred to [Zimmermann and Frejinger \(2019\)](#).

In this paper we focus on learning the utility function of stochastic path choice models, which are based on more realistic assumptions of human behavior than the deterministic counterparts. In the next section, we present the most widely used methodology in this context, namely discrete choice modeling.

Discrete Choice Models

Discrete choice models are stochastic demand models grounded in random utility maximization theory. They provide a methodology to statistically estimate parametric models of behavior where an individual makes a choice between a discrete number of alternatives, under the assumption that alternatives are associated with a random utility, and an individual's choice is the outcome of utility maximization. In the context of path choice, alternatives correspond to paths between an individual's OD pair.

Discrete choice models assume that the utility function is a parametric function of several attributes, usually linear-in-parameters. This parameterization allows to resolve the under-determinism which otherwise characterizes the inverse problem. Fitting the noisy path observations corresponds to finding the parameters which minimize the error of the data, which is measured by the log-likelihood loss. In other words, the model's parameters are selected by maximum likelihood estimation, such that the estimated parameters $\hat{\beta}$ maximize the probability of the observations $n = 1, \dots, N$,

$$\hat{\beta} = \arg \max_{\beta} \ln \prod_{n=1}^N P_n(i; \beta), \quad (1)$$

where $P_n(i; \beta)$ is the probability of path alternative i chosen by individual n . Note that we use the same notation for individuals and observations implicitly assuming that we do not have panel data.

Inherent to the problem of path choice is a combinatorial challenge, due to the exponential number of paths connecting each OD pair in real networks. Indeed, in practice it is impossible to enumerate all the paths an individual could choose from between an OD pair. Hence it is difficult to specify the form of the probability distribution: over which paths should the probability be defined? If all paths, how to define the support for probability distribution without resorting to enumeration?

The literature is well acquainted with this issue. As a result, there exist two kinds of discrete choice models — path-based and arc-based — which propose each a different solution, introduced in the subsequent sections. In the former, the action of choosing a path is modeled in two steps, while in the latter, it is modeled as a sequential process of arc choices. In the following sections, we detail how a discrete choice model can be estimated and used for prediction with each approach.

Path-Based Models

In path-based models, the probability distribution over paths for an individual n traveling between a given OD is defined in two steps as follows.

1. The modeler restricts the number of paths to a certain individual specific choice set, denoted C_n . Most of the choice set generation algorithms (see, e.g., [Prato, 2009](#)) generate path alternatives by iteratively computing shortest paths according to different generalized cost functions or on different network structures.
2. Paths not belonging to C_n are assigned a zero choice probability, while paths in C_n obtain a probability normalized by a constant computed over all paths in C_n .

The model's formulation relies on path-based variables. The utility of a path i is a random variable $u_i = v_i + \mu \varepsilon_i$, where ε_i is a random error term, μ is its scale, and v_i is the deterministic component of the utility parametrized by attributes, which can be additive over arcs or not. While not required, the deterministic utility is often linear in parameters, that is, $v_i = \beta^T x_i$, where β is a vector of parameters to be estimated and x_i is a vector of attributes of the path i . Individuals are assumed to maximize random utility, therefore the probability of choosing an alternative $i \in C_n$ is given by:

$$P(i|C_n; \beta) = P(u_i > u_j, \forall i \neq j \in C_n). \quad (2)$$

The form of the path choice probability $P(i|C_n; \beta)$ depends on the distributional assumption on the error terms ε_i . The simplest model assumes i.i.d. Extreme Value Type I distributed error terms and is known under the name multinomial logit (MNL) or softmax in machine learning,

$$P(i|C_n; \beta) = \frac{e^{\frac{1}{\mu} v_i(\beta)}}{\sum_{j \in C} e^{\frac{1}{\mu} v_j(\beta)}}, \quad (3)$$

while more complex models account for correlation between path utilities in the stochastic part of the utility function. In the latter category, we note that there exists among others the paired combinatorial logit ([Pravinongvuth and Chen, 2005](#)) the cross-nested logit ([Vovsha and Bekhor, 1998](#)) and the mixed logit models (e.g., [Bekhor et al., 2002](#); [Frejinger and Bierlaire, 2007](#)).

In terms of complexity, the estimation of models, which introduce correlated error terms, is more costly, due to the additional model parameters and the nonconvexity introduced in the log-likelihood function. Furthermore, mixed logit models require to resort to simulated maximum likelihood estimation ([Train, 2009](#)). However, accounting for correlation between error terms allows to more correctly represent the perceived similarity between overlapping paths and thus improve the predicting accuracy of the models.

There exists an alternative approach to estimate path-based models based on the assumption that individuals may choose any path in the network, known as sampling of alternatives. It consists in correcting the path utilities for the sampling protocol, which generated the restricted choice sets ([Frejinger et al., 2009](#)). The correction requires an algorithm that samples paths with known probability, which is a difficult problem in itself ([Flötteröd and Bierlaire, 2013](#)). [Guevara and Ben-Akiva \(2013a, 2013b\)](#) show that it is possible to estimate mixed logit and multivariate extreme value logit models using sampling of alternatives. To the best of our knowledge, in a route choice context the use has been limited to the logit model with path size attribute ([Frejinger et al., 2009](#)) and cross-nested logit ([Lai and Bierlaire, 2015](#)). While the sampling approach allows to correct the utilities to obtain consistent estimates, it is unclear how to compute the path sampling correction for prediction. In the following we therefore discuss prediction with path-based models without sampling correction.

The estimated models, $P(i|C_n; \hat{\beta})$ where we denote the maximum likelihood estimates $\hat{\beta}$, can be used to predict path choice (simulation from the estimated probability distribution) or, based on a given OD matrix, to compute expected arc flows. Path-based models require to decompose the prediction problem by OD pair, and possibly further by category of individual. The latter is necessary if path utilities are a function of socio-economic characteristics of individuals. We denote OD specific choice sets C^{od} (which may, in addition, be specific to individual category). The corresponding demand g^{od} is then assigned proportionally to the

predicted choice probabilities for each path in C^{od} . Flow on arc a for a given OD pair can be obtained by summing the flows on all paths traversing arc a ,

$$f_a^{od} = \sum_{i \ni a} P(i|C^{od}; \hat{\beta}) g^{od}. \quad (4)$$

Total expected flow f_a on arc a can be obtained by summing over OD pairs,

$$f_a = \sum_{od} f_a^{od}. \quad (5)$$

Arc-Based Models

In arc-based models, the process of choosing a path i is modeled as a sequential process of arc choices. To be more precise, it is formulated as an undiscounted finite horizon Markov decision process with an absorbing state, which is the destination. Instead of reducing the number of options to a given choice set, each path is associated to a nonzero probability, corresponding to the product of the probability of choosing each arc composing the path. The choice of arc of an individual is independent of the trajectory followed up to this point, but may depend on the incoming arc. One reason to allow it is to account for turning angles. For this reason, we denote an ingoing arc k , and outgoing arcs from k are denoted $a \in \mathcal{A}(k)$.

The model is formulated with arc variables. The instantaneous deterministic utility of an arc a when coming from k is denoted $v(a|k)$. Implied is that there exists another component to an arcs's utility. The latter is called the value function, which represents the maximum expected utility to be gained from arc a until destination is reached. For an individual traveling to destination d , the random utility $u(a|k)$ of an outgoing arc a to k is then the sum of its instantaneous deterministic utility $v(a|k) = \beta^T x(a|k)$, an error term $\mu \varepsilon_a$, and the destination-specific value function V_a^d , that is,

$$u(a|k) = v(a|k) + \mu \varepsilon_a + V_a^d. \quad (6)$$

The value function is defined recursively according to the Bellman equation:

$$V_k^d = \begin{cases} 0, & k = d, \\ E_\varepsilon [\max_{a \in \mathcal{A}(k)} \{v(a|k) + \mu \varepsilon_a + V_a^d\}], & \forall k \in \mathcal{A}. \end{cases} \quad (7)$$

Similarly to path-based models, arc-based recursive models can allow random terms to be correlated or not. The standard assumption of i.i.d. Extreme Value Type I error terms yields the recursive logit (RL) model (Fosgerau et al., 2013). However there exists several arc-based models accounting for correlation between path utilities, notably the nested recursive logit (NRL), the mixed recursive logit (MRL), and the recursive crossnested logit (RCNL) models (Mai, 2016; Mai et al., 2015; Mai et al., 2018). Moreover, Oyama and Hato (2017) use a discounted RL model to analyze travel behavior in a network going into gridlock.

Both the RL and the NRL are based on an MNL model over the outgoing arcs, the difference being that the NRL possesses arc-specific scale parameters μ_k . In more complex models such as the RCNL, each arc choice situation is modeled with a multivariate extreme value model. In general, the choice probability $P(i; \beta)$ of a path i consisting of a sequence of arcs $k_0, k_1, \dots, k_T$ is given by the product of arc choice probabilities:

$$P(i; \beta) = \prod_{j=0}^{T-1} P^d(k_{j+1}|k_j; \beta) \quad (8)$$

When arc choice probabilities $P^d(k_{j+1}|k_j; \beta)$ correspond to an MNL with fixed scale μ , the RL path choice probability takes a simple form and is equivalent to that of a path-based model with unrestricted choice set. In this case, arc choice probabilities are given by:

$$P^d(a|k; \beta) = \frac{e^{\frac{1}{\mu} v(a|k; \beta) + V_a^d(a| \beta)}}{\sum_{a' \in \mathcal{A}(k)} e^{\frac{1}{\mu} v(a'|k; \beta) + V_{a'}^d(a' | \beta)}} \quad (9)$$

The value function in this case can also be conveniently computed by solving a system of linear equation. In contrast, all models which relax the assumption of i.i.d error terms are computationally more costly to estimate, in part because the value functions are more complex to solve and because the log-likelihood becomes non convex.

In order to compute the log-likelihood in Eq. (1), path choice probabilities in Eq. (8) can be used. However, those require to solve the value function in Eq. (7), since arc choice probabilities depend on it. Hence the model is usually estimated using the nested fixed point algorithm, which consists of an outer loop which searches over the parameter space, and an inner loop which solves the value function for each trial value of β (Rust, 1987).

In order to predict arc flows from an OD matrix, recursive route choice models offer two approaches, namely (i) simulation, and (ii) solving a system of linear equations, as in, for example, Baillon and Cominetti (2008). The latter allows to decompose the problem by destination only. Indeed, arc flows f^d to destination d can be obtained as the result of the destination specific system:

$$f^d = (I - P^d(\hat{\beta})^T)^{-1} g^d, \quad (10)$$

where g^d is the demand vector from all origins to destination d , and $P^d(\hat{\beta})$ is the estimated matrix of arc choice probabilities to destination d , where $P^d_{k,a}$ represents the choice probability of outgoing arc a from arc k . It then suffices to sum the destination specific flows in order to obtain the vector of total arc flows f ,

$$f = \sum_d f^d. \quad (11)$$

Traffic Flow Prediction and Related Problems

Path choice predictions — Eqs. (2) and (8) — or predicted arc flows — Eqs. (5) and (10) — are rarely useful on their own, rather, they are central components in models of other problems that depend on path choice predictions. In this context, network design (Magnanti and Wong, 1984) constitutes an important class of problems and encompass, for example, facility location, network pricing and flow capture. We devote section, “Bilevel Optimization and Network Design”, to bilevel optimization linking this class of problem to path choice modeling. First, however, it is important to discuss the role of congestion when computing traffic flows in networks with capacity restrictions. Indeed, if the network of interest is congested, then demand and supply interact and flows at a traffic equilibrium provide more useful information than the flows assuming an uncapacitated network as in Eqs. (5) and (10). A detailed discussion of network design and traffic equilibrium is clearly out of the scope of this article. Instead, we give a brief high-level description with the purpose to provide guidance on the trade-offs involved in the choice of a path choice model and its specification, that is, choice sets, distribution of error terms, and functional form of the utilities. We first focus on traffic assignment and equilibrium solutions followed by bilevel optimization.

Traffic Assignment and Equilibrium

Stochastic traffic assignment models are used to predict flow in a network under the assumption that travelers choose paths according to an additive random utility maximization model. Through attributes that depend on flow — for example, a link performance function that gives travel time as a function of flow — the utilities depend on capacity and interaction with other travelers in the network. A stochastic user equilibrium is reached when no user can unilaterally improve his/her utility by changing path (Daganzo and Sheffi, 1977). The equilibrium can in some cases be characterized as a solution to a minimization problem (e.g., Sheffi, 1985) and the associated solution algorithm is typically based on iterative stochastic traffic assignments.

As can clearly be seen in Eqs. (5) and (10), the assignment models rely on (i) a choice model and (ii) information on aggregate demand in the form of OD matrices. They state how many vehicles need to travel between each OD pair in a given time interval. We note that if the utilities of the path choice models depend on socioeconomic attributes of the travelers, then the OD matrices must be defined accordingly. In practice, the assignment is often limited to a few user categories each having an OD matrix and the utilities otherwise depend on network attributes only.

Through the path choice model, the traffic assignment crucially depends on the choice set assumption. The flows can be limited to a restricted network defined for each OD pair, either explicitly through the path choice sets (Bekhor et al., 2008), or implicitly as proposed by Dial (1971). A restricted network should be defined so that it comprises all alternatives having a utility high enough to attract nonzero flow. This means that the definition of a restricted network needs to be updated if network attributes, such as travel times change, or if the structure of the network itself change, for example by the addition or removal of arcs. As opposed to this restricted network assumption, Baillon and Cominetti (2008) propose a Markovian traffic equilibrium (MTE) for unrestricted networks (MTE extends other works, for example, Akamatsu, 1996; Bell, 1995, that also avoid the assumption of a restricted network). The model relies on an arc-based path choice model defined by destination specific arc choice probability matrix. It is sufficient that the latter is a stochastic matrix; hence, it is not limited to a specific choice model.

An important practical use of assignment and equilibrium solutions is the analysis and comparison of network scenarios, for example: How do the flows in the network change if we increase speed on certain links? How do the flows in the network change if we add new infrastructure? The computation of an equilibrium solution (or assignment if the network is uncongested) allows to compare the different scenarios. Network design problems go beyond such simple scenario analysis and aim at finding the optimal network structure given demand.

Bilevel Optimization and Network Design

Bilevel optimization is suitable to model a hierarchical relationship between decision makers with possibly conflicting objectives (see, e.g., Colson et al., 2007, for an overview). The leader (upper-level problem) first makes decisions, then the followers (lower-level problem) make decisions according to their objective function that depends on the leader’s decisions. In our case, the leader takes network design decisions and the followers make path choices in the network. Important to emphasize is the link between the two optimization problems. The leader can anticipate the reactions of the followers which leads to a nested optimization problem where constraints in the upper-level problem involves decision variables from both levels. Bilevel optimization problems are non-convex and non-differentiable and even the simplest case when upper and lower problems are linear programs is known to be NP-hard (Jerusalem, 1985).

Bilevel optimization formulations of network design problems where users are assigned to deterministic shortest paths or where users achieve a deterministic user equilibrium are well studied (a few examples are Abdulaal and LeBlanc, 1979; Brotcorne et al., 2008; Labbé et al., 1998; Marcotte, 1986; Nair and Miller-Hooks, 2014). On the contrary, the literature on the stochastic counterpart where users are assigned to paths according to a discrete choice model is scarce. Exceptions are the series of works by Gilbert et al. (2014a, 2014b, 2015) devoted to the network pricing problem where the leader selects revenue-maximizing tolls on a subset of arcs in the network and the followers select random utility maximizing paths where the utilities depend on tolls, among other attributes. The stochastic variant leads to challenging nonlinear optimization problems with strong combinatorial features. Solution algorithms rely on reformulations to a single level and approximations which, in turn, depend on the analytical properties of the choice model. The aforementioned studies therefore use the nice properties of the logit and mixed logit models with utilities that are linear, at least in upper-level decision variables.

Given the importance of network design problems for applications where travelers are known to exhibit heterogeneous behavior, we believe that there are several promising avenues for future research related to bilevel optimization. First, modeling followers reactions according to choice models with better prediction accuracy than logit. Second, model followers' reaction through a stochastic user equilibrium solution, in which case the problem belongs to the class of mathematical programs with equilibrium constraints (MPEC).

Advantages and Drawbacks: Path-based Versus Arc-Based Models

In this section we discuss the advantages and drawbacks of the path and arc-based approaches to model path choice behavior in a network using discrete choice. The essential points are summarized in Table 1.

The majority of studies in the literature are based on the first approach, namely path-based models with generated choice sets, which are treated as the true ones. The major drawback of this approach is its reliance on path choice sets, which are costly to generate and may lead to biased parameter estimates (Frejinger et al., 2009). In turn, this can result in counterintuitive results and an inaccurate behavioral analysis. Its main advantage is that once choice sets of paths are specified, the model can be estimated with a standard software for maximum likelihood estimation. There exists several extensions of path-based models to incorporate correlation between path utilities, and any imaginable path attribute — additive over arcs or not — can be incorporated in the utility function, which makes this approach flexible in terms of model specification. Another drawback is yet related to prediction. Since predicted choice probabilities vary depending on the generated choice sets which are defined arbitrarily (i.e., without support from data) this approach can lead to predictions that are arbitrarily bad. Moreover, particular care has to be taken when path-based models are used for scenario analysis or as part of optimization. In this case choice sets need to be regenerated each time changes to the network occur. This is costly and also impact the comparison of scenarios as it can be unclear if a change in traffic flow is simply due to a change in the choice sets or a change to the network. In this context, counterintuitive results have been reported in the literature (Nassir et al., 2014) where an improvement to the network leads to worse accessibility (the reason for the results is explained in Zimmermann et al., 2017).

Path-based models with sampled choice sets belong to the approaches based on an unrestricted network. By estimating the models with a correction term that accounts for the path sampling protocol, the resulting parameter estimates are unbiased.

Table 1 Summary of advantages (+) and drawbacks (–) for each approach

Restricted network		Unrestricted network	
Path-based models with generated choice sets		Path-based models with sampled choice sets	Arc-based models
Estimation	+ Standard software – Parameter estimates may be biased – Choice sets costly to generate + Flexibility regarding models (correlated utilities) + Flexible utility specification	+ Standard software – Computation of a correction term – Choice sets costly to generated and limited choice of algorithms – Models limited because of correction term + Flexible utility specification	– Non standard software + Consistent parameter estimates – Computation of value functions + Some flexibility regarding models – Arc-additive utility specification
Prediction	– Potential re-generation of choice sets (per OD pair) – Predictions can be arbitrarily bad (depending on choice sets). Limitations when comparing network scenarios. – Predictions computed per OD pair	– Unclear how to use for prediction	– Computation of value functions (per D or O) + Accurate predictions that can be directly compared across scenarios + Predictions computed per D or O – Predicts paths with cycles with non-zero probability

Nevertheless, the costly necessity to generate choice sets remains, and the algorithms at disposal are restricted to those with known path sampling probabilities. A major drawback is that the model cannot predict according to the true estimated choice probabilities, since sampling choice sets is required for prediction as well. Therefore this approach is not recommended for applications, which go beyond the analysis of estimated parameters. We note that it is, however, possible to estimate models using sampled choice sets and then using an arc-based model for prediction, as in Zimmermann et al. (2018) who study activity-travel scheduling behavior.

Arc-based models overcome the main drawbacks of path-based models. The models can be consistently estimated without requiring any path choice sets. This necessity is replaced by the need to solve value functions at each step of the maximum likelihood estimation algorithm, which are quick to solve for the RL model, but more costly for the recursive counterparts which account for correlation. Since the estimation algorithm requires to solve the value functions as part of an inner algorithm when searching over the parameter space, non-standard estimation software is required. Some of the recursive models are implemented in MATLAB, in a code available online, supplemented by a tutorial detailing how to use it (<http://intermodal.iro.umontreal.ca/software.html>).

A potential downside is that the arc-based models require attributes that are additive over arcs, so nonadditive attributes, such as slope, need to be transformed into additive ones (Zimmermann et al., 2017). This can potentially be challenging and increase the size of the state space. Nevertheless, we note that although path-based models seem more flexible in this respect, their choice set generation step involve shortest path algorithms which, in turn, require arc-additive attributes.

Regarding prediction, the arc-based approach is the most straightforward and the only one which allows to predict path choices according to the true estimated probabilities even under network changes. Although value functions need to be solved for prediction, it need only be done once, as opposed to numerous times during estimation. Prediction is faster thanks to the fact that value functions are destination (or origin) specific as opposed to OD specific path choice sets. While arc-based models on an unrestricted network have several major advantages over path-based models, they have the drawback of assigning nonzero probability to paths with cycles (provided, of course, that the network contains cycles). It is clearly behaviorally unrealistic that travelers choose to make numerous cycles. Fosgerau et al. (2013) numerically investigate the issue and conclude on real data that the probability of even one cycle is very small. We note that if simulated path predictions are of interest and paths with cycles should not be considered, it is easy to detect cycles and truncate the distribution to noncyclic paths.

Conclusion and Perspectives

The problem of route choice modeling consists of learning the utility function of a rational cost-minimizing decision maker from data. Deterministic or stochastic models can be used to model route choice depending on the application and assumptions made on the data. Among stochastic models, discrete choice models are the most widely used in the transportation research community. This article gave an overview of that literature with the purpose to highlight advantages and drawbacks of existing discrete choice models, depending on their ultimate use. We detailed two main modeling approaches, namely path-based and arc-based models.

Path-based models essentially restrict the available choices a traveler can make in the network. This allows to keep users' modeled behavior within sensible limits, and typically prevents the improbable occurrence of cycles. Nevertheless, path-based models have important theoretical drawbacks both regarding estimation and prediction, which cannot be fully overcome by using sampling corrections as in Frejinger et al. (2009).

Arc-based models are based on an unrestricted network assumption by modeling the choice of paths arc by arc. It leads to a mathematically advantageous formulation, with unbiased parameter estimates as well as fast and accurate predictions.

Each approach possesses advantages and drawbacks. However, we believe that the efficiency and accuracy of the arc-based formulation largely overcome its flaws. Implementing the estimation and prediction of such models in standard software would therefore benefit transportation researchers and practitioners.

Background

Departure time choice models are either parts of travel demand modeling systems or stand-alone policy analysis tools necessary to investigate the temporal distribution of transportation demands. Modeling departure time choices intends to capture the preferences of travelers to specific time slots of the day to start out-of-home activities. Out-of-home activities require movement from one location to another location (defined as a trip). The choice of the departure time for an out-of-home activity is, in fact, the choice of the trip start time to the activity location (destination). Conventionally, departure time choice is modeled as opposed to arrival time (at destination location to start the activity) to recognize the uncertainty in transportation network performance and resulting randomness of travel time to reach the destination. Naturally, travelers tend to choose the time of departure for a trip with the expectation of travel time it would take to reach the destination. Depending on the purposes of destination activity and travel time uncertainty (resulting from dynamics of transportation network performance), different time-of-day can be feasible. For example, for work and school activities, activity start times are often fixed by the type and nature of work and school. In such a case, corresponding departure time choices may not have an extended period to choose from. Regular work and school start in the morning and ends in the afternoon. This can be different for people with flexibilities in work start times and work durations. In nonwork activities, such as shopping, recreational, and social activities, people may have more flexibility to choose departure times. In any case, modeling departure time choice is modeling the traveler's choice of a time-of-day to start a trip.

Departure time choice of the different trips of urban residences has profound implication to the performances of the urban transportation system (Ashiru et al., 2004). The peak and off-peak period of travel demand and corresponding congestion effects in transportation network are results of clustering of departure time choices at particular parts of the day. Objectives of departure time choice models include investigating daily travel behavior for future demand forecasting to specific transportation policy evaluations, for example, peak spreading, congestion pricing, high occupancy vehicle (HOV) lane usage, etc. Departure time choice model is pivotal to any demand modeling system in accurately capturing time-varying vehicle flow patterns on urban transportation networks, which is also called transportation system performance. Transportation system performances define the difference between the departure time of the trip and the arrival time to start the activity (the travel time of the trip). Schedule delay in terms of early arrival or late arrival and corresponding penalty (dissatisfaction) influence the dynamics of departure time choices. It has become customary that departure time choice is explicitly modeled and arrival time and early/late arrivals are estimated based on travel time to reach the destination.

Modeling the choice of departure time has been an important research question since the early 1970s. Earlier efforts to capture the effects of influencing factors of departure time choices are predominantly for car users. Later, the departure time choices of transit users are also being considered to investigate transit demand. Modeling departure time choices of commuting trips by car has been receiving continuous research focus. Researchers investigated whether transportation network performances (variation of travel time and cost for different starting points) alone or other factors influence the choice of departure time alternatives. Other factors include job-related attributes (arrival departure time flexibility, flexible duration of work), job category, job type, age, gender, income, and other socioeconomic factors.

Departure Time Choices

Departure time choice models can be different for different trip types as activity-scheduling constraints vary for different activity types. Also, the departure time choices of any trip can be correlated with the travel mode of the trip. Departure time choices of car

drivers can be different from the departure time choices of transit users. Similarly, departure time choice for carpool users can be different from the departure time choices of taxi and ride-sharing or ride sourcing services. The type and approach of modeling departure time choices can vary by the context of the application of the models. Generally, dealing with departure time choices can be part of:

1. A developing specific and stand-alone policy analysis tool
2. A traffic assignment model development
3. A demand modeling system

To develop a stand-alone policy analysis tool, explicit modeling of departure time choices of different modes for different activity type is conducted. Such models allow capturing effects of transportation system performances (travel time and cost), parking restrictions, business office hours, activity schedule flexibility, and various socioeconomic factors on the choice of departure time alternatives.

The significant difference between a static and a dynamic traffic assignment model to predict transportation network flow is that static assignment overlooks distribution of departure time choices of the travelers. Modeling dynamic traffic assignment requires explicit specification departure time choices either through aggregate departure time distribution or disaggregate departure time choice modeling. Aggregate departure time distribution is defined by patterns of departure time choices of urban residences as observed through travel surveys or the changing patterns of traffic volume on the networks. Disaggregate departure time models for dynamic traffic assignment can be discrete choice models or continuous time allocation (to different activity type) choice model.

Departure time choices are explicitly modeled for activity-based travel demand modeling systems (Habib, 2013, 2018). Typical four-stage urban transportation models usually consider static traffic assignment and so departure time choices for different trips are often overlooked. However, for activity-based travel demand model, it is customary that departure time choices of different activities that require making trips to the destination location are modeled through modeling activity scheduling. Alternative activity-scheduling approach includes:

- Use of univariate or joint econometric models for departure time choices of trips to form daily travel schedule.
- Use of behavioral rules to capture complicated processes of scheduling various activities with different flexibility, the priority of scheduling at specific parts of the day.
- Use of econometric models for the choices of departure times and time allocation to different activity types and then use of behavioral rules to form daily travel schedules.

In activity-scheduling model departure time, choices are often modeled jointly with travel mode choice to capture substitution patterns among a choice of different modes and different time-of-day options for departure choices. Similarly, a joint model of departure time choice and destination location choice can be with or without consideration of alternative mode choices. Such joint models are used to investigate complicated and multidimensional trade-off in daily activity-travel scheduling. Joint model refers to the use of probabilistic mathematical formulations of choice dimension with consideration of correlations among the choices that are modeled.

However, in any departure choice model (either stand-alone model or a part of demand modeling system), travel time to destination is considered as an expenditure to the scheduling process. So, travel time (as well as travel cost) is an exogenous variable to departure time choice model if travel route choice is not jointly modeled. In standard models, route choice is modeled separately. This raises the issue that the choices of departure times define traffic flow and thereby transportation network performances (travel time and cost) in turn influence the choices of departure time alternatives. In standard modeling practice, such cyclical relationship is tackled through iterative feedback between departure time choice and route choice models. However, it is possible to model departure time choices jointly with route choice with or without considering choices of alternative modes but is less common because of computational complexity it poses.

Modeling Techniques

Specific modeling techniques that are used for modeling departure time choices in various contexts and applications depend on whether the time is discretized into alternative time slots to choose from or the continuous nature of time variable needs to be preserved. Time discretization of a 24-hour day can be of:

- Big time chunks: Peak period, off-peak periods, shoulder (between peak and off-peak), etc. Such classification is based on efforts to capture patterns of traffic congestion throughout the day.
- Smaller time chunks: It can be of 15 minutes to a 1-hour time slot. Such classification intends to capture the fine-grained distribution of traffic load onto the network.

Discrete choice models that are used for modeling are multinomial logit model, nested logit model, generalized extreme value model, and mixed logit model (Bhat, 1998a, 1998b). Discrete choice models are based on the assumption of random utility

maximizing choice-making behavior that refers to the fact that a traveler maximizes satisfaction/utility in making a choice and a portion of such utility is random (cannot be explained by systematic variables). The difference among these discrete choice models is on the accommodation of correlation between two or multiple discrete departure time alternatives. Multinomial logit model considered all alternatives are independent, which may not always correct when adjacent time slots can be a positive correlation. Nested logit and generalized extreme value models allow group/nesting of alternatives with the possibility of having correlations in the choice model structure to overcome the limitations of the multinomial logit model. Mixed logit model provides a very flexible model structure to capture all sorts of correlation and substitution patterns in alternative departure time choices.

Considering time as a continuous entity and departure time choices are indirectly modeled through modeling time allocation choice:

- One approach of such a model can be based on the microeconomic theory of time allocation/consumption. The primary purpose of such an approach is to derive the perceived value of time (VOT). Using the assumption of marginal cost factors, VOT can be derived considering the choices of departure time alternatives. It requires a time expenditure function, which needs to be optimized under several time–space–money constraints. The continuous-time model can also be based on the hazard rate of activity duration. Dynamics of time expenditure to an ongoing activity can eventually define the departure time to the trip leading to the next activity. Such models are called hazard model, and the primary purpose of such models is to capture time expenditure dynamics.
- Another approach of continuous time model is based on activity-scheduling optimization under daily time budget (24 hours) constraints. Using Kuhn–Tucker optimality condition and microeconomic theory of the consumption process, such a model can capture various trade-off involved in daily activity scheduling. Such models are known as Multiple Discrete-Continuous Extreme Value (MDCEV) model.

In any of these econometric approaches of modeling departure time, choices can also give a useful economic evaluation measurement, which is the value of travel time savings (VOTTS). VOTTS is the marginal rate of substitution between travel time and money, which can be estimated by taking the ratio of the coefficients travel time and travel cost variables in the discrete or continuous choice model. However, since travel time is attributed to a travel mode, a generalized VOT derived from the departure time choice models needs to be weighted over all modes. Mode-specific departure time choices (modeled as separate departure time choice models for separate modes or a joint mode and departure time choice model) would give mode-specific VOTTS. The VOTTS, in context of departure time choices, is also attributed to the travel time uncertainty leading to early to late arrival compared to the desired/expected arrival time. Many of empirical econometric model primarily address the early arrival, and late arrival issue through the representation of reference-dependent choice behavior (e.g., prospect theory) as travelers response to these two may not be symmetric.

Data for Empirical Modeling

Departure time choice model that is explained in this paper is primarily empirical models and requires observed choice information (data) (Arellana et al., 2012). Departure time choice model estimation requires data that are usually collected through:

- Revealed preference (RP) surveys: Typically, travel surveys conducted among a sample of individuals from the study area. RP travel surveys can be of a specific type of trips, for example, commuting trips, shopping trips, social trips, etc., or general travel diary survey—RP travel diary surveys. Such data provide information on chosen departure times by the respondents in the sample.
- Stated Preference (SP) survey data are used to investigate sensitivities of various policy (pricing, time-of-day restriction, etc.) on the choice of departure time. SP surveys can be designed to capture various aspects of departure time choices including the effects of scheduled delays, congestion pricing, peak-period parking restriction, in-transit crowding (during peak hours) effects, etc. SP surveys use hypothetical scenarios of alternative departure time options with all attributes that differentiate or equate the alternatives. A sample of individuals is required to collect stated responses to those hypothetical scenarios, which provide data on behavioral trade-offs in departure time choices. Also, in recent year, joint RP-off-SP surveys are increasingly being used where the SP survey is built on an RP travel diary. First, RP travel diary is collected, and then the SP scenarios are built based on observed departure time choices in the RP data. Such a survey can much minimize hypothetical biases in SP data and also enrich the RP data through specific SP contexts.
- Mode-specific aggregate origin–destination (OD) level trip table data are often used for jointly modeling departure time choice and traffic assignment model. Such OD data can be collected through household travel surveys, transit smart card data, or other sources, for example, roadside counts, intercept survey, etc. However, these data can allow capturing the distribution of alternative departure time choices than disaggregate modeling of departure time choices.

RP data might not include specific information about the scheduled delay and corresponding effects on the chosen departure time choices unless that information was explicitly collected through the survey. In any case, estimating the parameters of a departure

time choice model through the use of RP data requires imputation of alternative level-of-service information (specifically travel time and travel cost) for non-chosen departure time alternatives. Typically, a calibrated and validated traffic assignment model for the study area is used to generate such information. Of course, the traffic assignment model needs to have the temporal specification that matches the specification of departure time choice alternatives. For example, if the departure time choice model considers peak and off-peak periods as alternatives, the traffic assignment model should be able to generate travel separate time and travel cost for those alternative periods too. However, if the departure time choice model considers hours or even shorter time slots as choice alternatives, the traffic assignment model needs to generate level-of-service variables at that fine grade too. Otherwise, departure time choice alternatives may become quality indifferent (not characterized by differences in level-of-service variables) alternatives. In such case, modeling choices are still possible but would capture more of the market share of departure choices than disaggregate choice trade-offs.

Policy Evaluations

Departure time choice models are used:

- To understand travel behavior of residents that needs to be captured in regional travel demand modeling system for accurately predicting transportation demands in the future or of changes in transportation or land-use system.
- To investigate demand-side policies, to curve traffic congestion, especially peak-period overuse of the overall road network, specific network elements (e.g., bridges, tunnel, etc.) transit service, etc.

Various travel demand management policies of land-use policies require a specific model of departure time choice of urban residences. Frequently, urban parking restrictions (on-street parking) and parking fees are used to facilitate commuting travel. For example, on-street parking restrictions on commuting corridors are often used to facilitate travel during the peak periods of the day. Evaluation of traffic management tools, for example, HOV lane usage and high occupancy tolled (HOT) lane usage, requires models that can capture the switching probability of departure times (with or without travel mode or routes) by the travelers in response to any such policies. Activity-based travel demand models are based on the concept of time-space constraints that refer to the facts that travelers can adjust activity schedules (activity start time and/or trip departure time) in response to transportation network performances. So, departure time choices are explicitly captured in activity-based models.

Conclusions

Departure time choice models are essential policy analysis tools used by transportation planners, traffic engineers, and transportation and land-use policy analyst. The objective of a departure time choice model is to capture how (or whether) travelers change their choice of trip scheduling (trip departure time). Departure time choices of all travel mode users (car user and transit users) have relevance to urban transportation performances as these define the peak-period traffic congestion levels on road networks and peak-period transit crowding on the transit network. Different type of modeling approaches is used for departure time choice. However, the predominantly econometric approach is prevalent. Econometric approaches used behavioral theory to define the choice model specification and observed data to develop an empirical model. Both aggregate and disaggregate choice models are used to investigate departure time behavior. Data from RP travel diary, as well as SP surveys, are used to estimate departure time choice model parameters. Departure time choice model can work as a stand-alone policy analysis tool to investigate specific transportation policies, for example, parking policy, congestion pricing, lane restrictions, transit crowding, etc. However, activity-based travel demands modeling systems explicitly capture departure time choices through activity-scheduling models. Various types of activity-scheduling models exist, for example, as the rule-based approach, econometric modeling approach, and hybrid rule and econometric approach. For the econometric model of departure time choices, modeling techniques vary based on the specification of time to define departure time choices. The discretization of time allows the use of discrete choice models, and continuous time specification requires optimization of time allocation approach. With a wide variety of possible departure time choice models, users of the model require to choose an approach and technique that suits the purpose of using the model as well as data availability for empirical model development.

Introduction

A transportation system is a supply–demand framework seeking equilibrium, wherein transportation services and infrastructure serve as the supply side and individual travel needs and desires serve as the demand side. Degradation on either side of the equilibrium results in imbalance leading to undesirable effects on the system as a whole. Congestion caused by, for example, morning commute travel demand exceeding roadway capacity is the most perceptible example of such undesirable effects of equilibrium imbalance in transportation systems (Vickrey, 1969). Any event interpreted as undesirable or cumbersome on personal resources motivates change. Change as such is characteristic of a response-mitigation measure against the undesirable effect(s) caused by the imbalance. This text explores individual level responses to congestion categorized into tactical and strategic measures and their culminating effects on the urban form.

Let us define “transportation supply” as the infrastructure and services that seek to satisfy travel demand. Let us define “congestion” as the degradation, due to crowding, of any transportation supply element. Congestion can therefore refer, as it most often does, to the reduction in travel speeds of a roadway due to vehicle demand exceeding available roadway supply. But it can also refer to a public transportation vehicle that no longer accommodates every passenger that would like to ride or to sit. Or a dedicated bicycle path in which travelers must moderate their speed due to the presence of other cyclists.

Congestion is a key driver of changes in traveler behavior, both tactical and strategic. For the purposes of this entry, let us define tactical changes in travel behavior as decisions that may vary day to day and have a relatively low switching cost whereas strategic changes have high switching costs. In aggregate, individual responses to congestion have profound impacts on urban form and land consumption. In fact, responses to congestion are arguably the most important influence on urban settlement patterns over the prior 80 years.

An inventory of potential tactical and strategic changes are introduced and defined in the next section, paired with a discussion of the implications of the response, both to individuals and society. Thereafter, a section discusses the degree to which the relationship between congestion and each behavior is well understood and readily predicted. A concluding section completes the entry.

Inventory of Behavioral Responses and Traveler Implications

Table 1 introduces potential behavioral responses to an increase in congestion and maps these responses on a qualitative scale of tactical to strategic (National Academies of Sciences, Engineering, and Medicine, 1994; Deakin, 1994).

An explication of each of the earlier responses is provided later, along with commentary regarding the impact of the change to an individual and the collective impact on society.

Changes in Route

A roadway traveler faced with steadily increasing congestion on a freeway may experiment with alternate routes. Similarly, a transit commuter faced with a rail or bus service that is uncomfortably crowded and/or difficult to board due to crowding may seek an

Table 1 Introduction and mapping of traveler responses

Item	Response	Tactical → strategic

3.	Changes in itineraries/stop-making	
4.	Change in temporary workplace location, that is, satellite office or working from home	
5.	Changes in travel mode	
6.	Vehicle upgrade	
7.	Within-region residential or employment location change	
8.	Outside-region residential and employment location change	

alternate route. The switching cost here is typically low, hence the mapping in **Table 1** of this behavior to the far end of the tactical side of the chart.

The implications to individuals of switching routes are minor, for example, traveling on local roads rather than freeways and having to endure more frequent encounters with intersection controls. With modern navigation applications on smartphones assisting travelers in finding lower cost routes, any gain from changing routes is likely to be short-lived, as other travelers are likely switching as well, shifting congestion accordingly.

The collective implications to a society of individuals switching routes are broader and generally negative. Roadways that are designed to accommodate small volumes of vehicles traveling at low speeds are not well suited for daily commuters seeking to move faster than, say, an adjacent congested freeway. Formerly quiet neighborhood streets may become less quiet and less safe for children traveling to school, or myriad other human activities that are incompatible with fast moving vehicular movements. Communities are therefore motivated to accommodate peak travel conditions on limited access freeways or other high-capacity facilities. This desire to accommodate peak travel, in turn, results in the construction of roadway facilities designed to try and meet peak demand, which, in turn, consumes land and shapes urban form—often expanding the footprint of urban settlements, separating neighborhoods with difficult-to-cross infrastructure, forming new communities, etc.

Changes in Departure Time/Scheduling

Congestion tends to occur during the morning and evening commute periods due to the convenience of a majority of work taking place during a common period of time—preferably when the sun is out. Travel demand, therefore, frequently exceeds available supply during these time periods; travelers with the ability to do so can travel outside of commute hours to avoid or mitigate the impacts of congested conditions.

Travelers with this flexibility often gain time after shifting their commute to earlier (or later) in the morning inbound and earlier (or later) in the evening outbound. Public transportation commuters shifting time can benefit from more available and/or convenient parking at suburban park and ride stations, as well as a place to sit on crowded transit lines.

The collective spreading of travel through the day is generally seen as a worthy public policy goal, with numerous governments implementing surcharges (often called “congestion pricing”) to cross bridges or board transit vehicles or enter a central business district during commute hours. A more even distribution of demand through the day makes it easier for transport authorities to manage their systems. Congestion pricing does have its critics, as for those without the flexibility at home or at work to change the time during which they travel, a congestion fee is an unavoidable tax on travel. This tax pushes against the utility toward common travel during the commute periods, as evidenced by its popularity—which motivated the congestion price in the first place.

As the congested travel period continues to expand, shifts farther and farther from common work hours begin to have disruptive and negative impacts on travelers’ lives. These can include:

- Reduction in time spent with family;
- Reduction in exposure to daylight; and
- Reduction in exposure to colleagues.

Changes in Itineraries/Stop-Making

After dropping the kids at school, a traveler may have just enough time to read the paper and have a coffee at a nearby coffee shop prior to traveling to work. An increase in congestion may motivate the elimination of the stop at the coffee shop. Similarly, a commuter may choose, if given the option, a so-called 9/80 schedule, in which, over a 2-week period, 8 days are spent working 9 hours per day, a 9th working 8 hours, and a 10th, typically every other Friday, taken off. As congestion increases, itineraries may change, with more time devoted to travel and less time devoted to activities.

As with the changes in departure time/scheduling, government actions that change itineraries are generally seen as a good public policy. Ample research exists on the benefits of motivating trip chaining behavior, where travelers are nudged to, for example, stop at

the grocery store on the way home from work rather than return home and then make a separate trip to the grocery store. In a vehicle fleet dominated by internal combustion engines, such trip chaining can result in reduced vehicle emissions, by reducing travel as well as the so-called “cold” engine starts. These collective benefits do come at a negative cost to individuals. Returning home prior to grocery shopping may allow a commuter to take the dog for a quick walk, use the restroom, or check on the garden. There is a reason a nudge is often needed for a trip chain to form: doing so is, for one reason or another, not ideal.

Change in Temporary Workplace Location

As congestion makes commuting increasingly onerous, travelers may opt to work 1 or 2 days a week in another location. This location may include home in a telecommuting arrangement, and it may include a satellite office. Many firms are now keeping small, headquarter addresses in high-status locations such as Manhattan or San Francisco, and moving the majority of operations to lower cost, often suburban, locations. These suburban locations provide less expensive real estate for the firm and—often—shorter commutes for workers. For workers that must spend most of their time in a city center location, satellite offices may offer a temporary respite from congestion.

The collective implications of employers moving to the suburbs—either to form satellite offices or to abandon the central city altogether—are profound. As employers move to the suburbs, households follow, allowing for the previously idealized situation of both living and working in a suburban setting. Working and living in the suburbs was the original promise of Silicon Valley. Once located in suburban locations, employment centers motivate the development of residential suburbs a bit farther away from the city center. When faced with commuting to two separate suburban office locations, two worker families may choose to live in yet another suburban community between the respective employment sites, motivating the creation of yet another residential suburban community. Many cities that came of age in the 1960s—Atlanta, Phoenix, Silicon Valley, Houston—reveal this development pattern. While such satellite workplace arrangements have the ability to relieve congestion from city centers and create jobs in suburban jurisdictions, they tend to redirect significant traffic toward the outlying suburban thoroughfares incapable of handling such congestion (Cervero, 1989). Between-suburb commuting is difficult to serve efficiently with public transportation, hence the need for very large investments in roadway infrastructure in these types of places over the last 50 years.

Changes in Travel Mode

As congestion makes traveling by automobile less convenient, public transportation often becomes relatively more convenient. In large, dense urban areas, such as New York City, traveling by public transport is often faster than driving and, in fact, is often the reason cities like New York have become as dense and prosperous as they are.

Increasing the encumbrance of automobile travel in order to motivate travelers to select alternate travel modes, including public transport, is generally viewed as a worthy public policy goal, as these modes generally have a smaller environmental impact than traveling by automobile. Individually, switching to a less crowded mode is generally undesirable, as there is a reason the other mode was chosen by the traveler as well as the numerous other travelers that make the switched-from mode crowded in the first place. Travelers who struggle to walk, climb stairs, or find confinement in shared spaces unpleasant face significant challenges when nudged away from automobiles, as do those traveling with young children. Overall, the benefits of high-quality infrastructure aimed at mitigating the impact of congested roadways can be seen in our densest cities, which provide high levels of accessibility to large numbers of individuals. Over time, these dense areas must continue to invest in nonautomobile infrastructure to avoid crowding on public transit routes—particularly subways—as crowding on desirable transit services shifts travelers to even less desirable modes (for most), including bicycles and buses.

Vehicle/Equipment Upgrade

When faced with an automobile commute that continues to increase as congestion increases, many travelers may mitigate the impacts of spending a lot of time in a vehicle by purchasing a new vehicle. For the past few decades, common amenity upgrades included automatic transmissions, climate control, and entertainment/communication systems. In decades to come, these amenities may include electric motors and automation. A present question of keen interest to travel behavior researchers is how travelers will value time spent in an automated vehicle. On the one hand, many travelers have the option of riding—rather than driving—in a vehicle today and express little enthusiasm in doing so, for example, it is not common to hear what a great time a friend/colleague had riding in a car on the way to work. On the other hand, automation will allow travelers to be alone in their vehicles and this isolation, paired with a freedom to move around, may make all the difference, as the ability to sleep, work, eat, exercise, etc., without the social pressures of a fellow traveler sitting 2 feet away or the restrictions of sitting in a crash-ready position, may be a highly tolerable-to-enjoyable experience.

Collectively, vehicle upgrades have mixed impacts on society. On the positive side of the ledger, new vehicles are generally safer and pollute less than older vehicles. On the negative side, automobile travel is still generally harmful to the environment and urban form.

In the same category as a vehicle upgrade is any other manner of equipment that may make commuting on any mode of travel more tolerable, including an electric bicycle, audiobook subscription, or high-quality headphones.

Within-Region Residential or Employment Location Change

When travel becomes unpleasant, a more dramatic and strategic change is to move—changing your home or work location. As noted in the temporary workplace section earlier, changing jobs to a firm with an office location closer to your home, particularly if your home is in a suburban location, has profound impacts on urban form and may, in fact, be the most important driver of changes in urban form that we have experienced over the last 60 years.

Changes in residential location also come with high transaction costs. The urbanization of formerly industrial areas of dense cities has mitigated the impacts of the suburbanization of employment. Consider, for example, the large number of condominiums now present in the South of Market neighborhood in San Francisco, the Pearl District neighborhood in Portland Oregon, and the Hudson Yards neighborhood in New York City.

The individual impact of changing jobs or homes can be significant, as it has the potential to disrupt a positive family dynamic often composed of the school and work locations of other household members. Further, moving to a work location away from a dense urban job center has the potential to reduce career earnings, as commute convenience is favored over proximity to other potential employers. The change can also be positive, as inertia may be responsible for families to remain in suboptimal housing situations after, for example, children leave home.

The collective impacts of changing residential or employment locations are generally negative, as these responses are a signal that the community has failed to provide sufficient transport services. Abundant inefficiencies result, including the formation of new cities, with the commensurate administrative overhead, the construction of costly and underutilized suburban freeways, increased self-segregation by socioeconomic class, and/or consumption of open-space/natural habitats.

Outside-Region Residential and Employment Location Change

A logical escalation of within-region residential or employment change is an outside-region residential and employment change. As noted earlier, an important motivation of the large increase in population of previously low population areas such as Phoenix, Atlanta, and Dallas is the ability to travel in an automobile with low levels of congestion (affordable housing and air conditioning's ability to make a warm climate pleasant are also key drivers). Had coastal cities such as Boston, Los Angeles, Washington, and San Francisco (1) invested in the types of public transport system that allows cities such as New York to grow larger and more dense, and (2) allowed the tall buildings necessary to accommodate a growing city, the populations of cities with less desirable amenities would, all else equal, be lower—potentially much lower. One could argue that the existence of all large, metropolitan areas in the Southwest, South, and Southeast regions of the United States is due in part by the desire of individuals to travel in an automobile in uncongested conditions.

The individual impact of relocating to a less congested area is generally negative, as the region with less congestion is logically of lower amenity than the region of higher congestion. Further, moving to a lower population area may result in few employment opportunities.

The collective impact of coastal cities failing to accommodate larger populations is difficult to understate—estimates have placed the cost at around \$1 trillion annually (Hsieh and Moretti, 2019). Transportation plays a key role in the decision not to get larger: opponents often cite increases in traffic or difficulty in parking as a reason to oppose development.

Understanding and Ability to Predict

Sound public policy can mitigate the impacts of congestion on individuals and society if the relevant phenomena are well understood and readily predicted. Table 2 summarizes the same behavioral responses identified in Table 1 and discussed earlier. The symbols now suggest the difficulty in making predictions in response to congestion.

The field of travel demand forecasting has embraced the challenge of predicting responses to congestion for the past several decades, motivated by a mandate from the United States Federal Government to comment on the likelihood that transport

Table 2 Introduction and mapping of traveler responses

Item	Response	Hard to predict → easy to predict
1.	Changes in route	□□□□□□□□□□
2.	Changes in departure time/scheduling	□□□□□□□□□□
3.	Changes in itineraries/stop-making	□□□□□□□□□□

7.	Within-region residential or employment location change	□□□□□□□□□□
8.	Outside-region residential and employment location change	□□□□□□□□□□

infrastructure and policies will reduce vehicle emissions. Travel modeling systems built for regional governments have long focused on making accurate predictions in regards to changes in route (item 1 in Table 2) and mode choice (item 5). The other tactical responses to congestion are more nuanced and difficult to predict. While changes in departure time/scheduling (item 2) and changes in itineraries (item 3) are easy to predict in the aggregate, simulating individual responses is a challenge, as individual preferences, employment considerations, and family considerations are difficult to observe. Understanding of such constraints has led to a shift in travel analysis and policy research from system management to demand management, with increased interest in ridesharing incentives, congestion pricing, and employer-based demand management schemes (Pinjari and Bhat, 2011). One such advance that has seen significant increase in transportation research and development interests is the prospects of autonomous vehicles. Research findings indicate that autonomous vehicles are expected to not only mitigate congestion but also improve vehicle safety and fuel efficiency, with an expected cost reduction ranging from USD\$2000 to USD\$4000 USD per vehicle (Bagloee et al., 2016; Fagnant and Kockelman, 2015; Lamotte et al., 2017). While autonomous vehicles may emerge as an ideal solution to urban congestion, their implementation, interaction with existing systems, mass-market penetration, and legal liabilities remain highly uncertain.

The field of land-use modeling deals with the more strategic aspects of congestion responses, including changing residential or employment location (item 7) and migration (item 8). Research suggests a strong correlation between household-level automobile ownership and residential density (Pushkarev and Zupan, 1977; Mogridge, 1997; Kitamura and Mokhtarian, 1997). Growing advocacy among land-use planners to promote residential density and mixed use developments stem from findings that travel patterns are derived from individual needs and demands for activities and accessing services (Cervero, 1995; Salomon and Mokhtarian, 1998). In other words, the change in spatial distribution of such attraction hubs within close proximity to residential locations could result in reduced travel time, congestion, and ultimately reducing or eliminating the need to consider a change in residential and/or employment location or migration.

Conclusions

This entry identifies and discusses the implications of travel congestion on traveler behavior and, in turn, urban form and other urban phenomena. Congestion is a significant driver of urban form at the local, regional, state, and national level. A brief section then comments on our ability to accurately predict these responses.

Origin–destination (OD) demand, which is also referred to as OD travel or traffic demand, corresponds to the traffic flow (in terms of total number of travelers or vehicles) between two traffic zones (namely origin and destination zones) during a study period. In a spatial manner, the OD matrix consists of defining a two-dimensional table whose rows and columns represent the traffic zones, in which the entry of the OD matrix is the OD demand between the corresponding two traffic zones. OD demand is regarded as the essential data required for transportation planning and traffic management. Therefore, researchers and practitioners have continued to explore new models for OD demand estimation.

In the middle of 20th century with launch of the computers, some developed countries in Europe and America began to investigate the traffic demand forecasting models in order to predict the needs of large-scale transportation infrastructure projects for urban development. By the 1970s, a representative “four-stages” urban traffic demand forecasting model had been proposed. The four-stages model divides the process of traffic demand forecasting into four stages, namely (1) trip generation, (2) trip distribution, (3) modal split, and (4) trip assignment. OD estimation, corresponding to the trip distribution stage, has attracted an increasing attention since then.

In reality, the complete information of actual OD demand cannot be accessed easily. In the past decades, researchers have proposed various models to estimate the OD demand on the basis of different approaches. These existing models can be classified by several criteria later. In the temporal manner, the OD estimation models can be classified as static and dynamic models. Considering the network uncertainty issue, the OD estimation model can be categorized as deterministic and stochastic OD estimation models. Regardless of different criteria for grouping the OD estimation models, one common feature of OD demand estimation model is to use the observed data, which contain the partial information of OD demand, in order to estimate the complete OD demand matrix under different scenarios. In view of this, this chapter addresses the up-to-date existing OD estimation models with respect to different sources of observed data used for various models.

Fig. 1 shows classification of these available OD estimation models with different sources of data and modeling approaches. With the fast-growing development of communication technologies, more and more sources of relevant data are available for OD demand estimation. At the early stage for development of the traditional top-down approach for OD estimation, survey-based models were used in practice in spite of its limited sample size and the vast amount of time and monetary consuming for collection of sampled OD data. Later, benefiting from the traffic flow data collected by traffic counting sensors (e.g., loop detector), a large body of bottom-up models for OD estimation from partial traffic counts were proposed and widely used by the researchers and practitioners. Nowadays, owing to the progress of Big Data science, multiple sources of data are now available for estimation of the OD demand matrix. A brief account of these existing OD estimation models is given later for review.

Survey-Based Models

Intuitively, the OD demand information can be obtained by the top-down approach with use of the survey-based methods and limited sample size, such as home-based survey, roadside interview, and license plate recognition technique. Home-based surveys together with census tracts have been empirical foundation for traffic demand forecasting models to capture many important demographic and travel characteristics of the households. For example, household interview surveys that have higher response rates and larger sample sizes can provide us reliable information on trip generation and distribution by traffic zones. With these sampled information, it follows with estimation of the complete OD trip matrix between traffic zones. These methods can yield accurate results when sufficient sampled households have been selected systematically for collection of the relevant travel

Figure 1 Classification of OD estimation models.

characteristics information. However, it is often costly and requires a large amount of resources for implementation of these household interview surveys.

On the contrary, roadside interviews have also been used to collect travel data on people passing through a specific location (OD station). By locating a series of these stations around the perimeter of the study area, it is possible to measure the travel into and/or through the selected area. With this survey method, drivers are stopped on the road and questioned as to their origin, destination, trip purpose, and associated travel characteristics data. However, this network-wide survey-based method is difficult for larger study areas and/or impossible to undertake frequently, notwithstanding the advancement in traffic survey technologies such as license plate recognition techniques.

Traffic-Count-Data-Based Models

Static OD Estimation Model

In view of the lower cost of the bottom-up approach, traffic flows collected by traffic counting sensors (e.g., loop detectors) have been widely used for OD demand estimation. The traffic-count data motivate transportation researchers to develop advanced models for OD estimation, which are well received by transportation practitioners. The key idea of OD demand estimation model based on traffic-count data is to estimate the OD demand so as to reproduce the resultant link flows which are consistent with the observed link flows at selected sensor locations. Most of these traffic-count-data-based models early developed are concentrated on the static OD demand estimation using optimization and/or statistical methods with partial network data (traffic counts on partial of the network links).

Optimization method: The OD estimation models using optimization method aim to minimize the difference between observed and estimated traffic flows. Such difference is usually formulated as the objective function. For example, suppose that the OD demand is the deterministic variable to be estimated, an optimization model can be proposed that yields the most likely OD matrix using an entropy-type objective function, in which the estimated link flows are consistent with measurements of traffic flows on selected links installed with traffic counting sensors. With consideration of the network congestion effects, [Yang et al. \(1992\)](#) extended Bell's model ([Bell, 1991](#)) and proposed a bi-level programming model for estimation of the OD demand from traffic counts. The upper-level problem is to minimize an entropy/or generalized least squares objective function, and the lower level is a traffic assignment problem to model the travelers' path choice behavior under congestion. In order to assess the performance of these bottom-up models, the quality of the OD estimation can be evaluated using different measures, such as the maximum possible relative error for OD demand estimates which is the relative deviation of the estimated OD demands from the true ones.

Statistical method: In view of the statistical properties of the traffic count data, some researchers adopted statistic methods to address the OD estimation problem. For example, the likelihood function is used in the maximum likelihood estimation method based on some probability distribution, such as Poisson distribution, to estimate the OD demand matrix. Some issues are considered in these statistical models, such as the presence of measurement and sampling errors in the observed link flows. The Bayesian estimator for OD estimation is another kind of statistical model. [Hazelton \(2000\)](#) considered the problem of estimating the OD traffic intensities with the given link flow data from an uncongested network over a number of time periods. The variation of route choice proportions could be captured with use of Poisson distributed OD flows. In view of the network uncertainties due to congestion, the mean and covariance of OD demand in a spatial manner can be simultaneously estimated using the least squares method or Lasso method.

Dynamic OD Estimation Model

Based on various static OD estimation models from traffic counts, some researchers investigated the dynamic OD demand estimation problem. Different from the static OD estimation model, the temporal information of the OD traffic flows is also considered in these dynamic models. For example, dynamic path flow estimators using time-varying traffic counts were developed to estimate the time-varying OD flows by path within the study networks. If more information, besides the traffic counts, can be obtained, the dynamic OD demand matrices can be estimated using different ways of the static models. For example, a path flow-based optimization model, which incorporates heterogeneous sources of traffic measurements and does not require explicit dynamic link-path incidences, was proposed to estimate the dynamic OD demand. Alternatively, Zhou and Mahmassani (2006) proposed a dynamic OD estimation model by extracting valuable point-to-point split-fraction information from automatic vehicle identification (AVI) counts without estimating market-penetration rates and identification rates of AVI tags.

Multiple Sources of Data-Based Model

Although various OD estimation models have been proposed in the literature, it is well known that a common difficulty of the existing OD demand estimation models is the solution identifiability problem, that is, it is impossible to uniquely identify the optimal OD demand matrix as the number of observed links (from which the traffic counts are available) is usually less than the number of elements to be estimated in the OD demand matrix. It is generally believed that the more information provided, the more accurate is the OD estimates. Thus, more and more sources of traffic data can be used for improving the OD estimation accuracy.

Multiple Sources of Traffic Data

In the age of Big Data, the AVI technologies, including license-plate-based AVI systems and cellular-phone-based AVI systems, have been studied extensively. The license-plate-based AVI system collects the vehicle license information and the time stamps that the vehicles pass by the detection point. Although the corresponding AVI data are more convenient to derive the OD demand matrix, the network-wide data collection is difficult due to low coverage of the license-plate-based AVI sensors. Currently, cellular phones have been widely used by travelers. Thus, the cellular-phone-based AVI data may be more convenient to collect for estimation of the OD demand matrix.

Global positioning system (GPS) can collect data for multiple-day trips, including departure and arrival times at origins and destinations, respectively, which directly records the OD demands by time of day. The aggregated GPS trajectory data are regarded as low-cost survey data, which can be used to reproduce the OD trip flows in both the spatial and temporal dimensions. However, attention should be given on two important issues when using GPS data, that is, the high measurement errors and low market penetration rates.

Radio frequency identification (RFID) is an emerging technology to collect AVI data. The RFID is a technology deployed in some cities to monitor traffic through detecting RFID tag-equipped vehicles passing by RFID detectors installed along the major road links. Information from RFID is more accurate, real time, and less influenced by the external environment as compared with the license-plate-based or the cellular-phone-based AVI sensors. The RFID data were utilized to derive the sampled OD demand matrix with use of the dynamic traffic assignment by matching the RFID data detected at origins and destinations along the selected road links.

OD Estimation Models

Methodologically, there are three types of the bottom-up models for OD demand estimation with use of multiple sources of traffic data. Apart from statistical and optimization methods, machine learning method can also be utilized to solve the OD estimation problem in view of the advanced development of artificial intelligence techniques.

Statistical method: This approach is based on the knowledge and methods of statistics. Researchers adopted statistical methods to dig out more information for estimation of the stochastic OD demand. For example, the particle filter has been used to estimate the probability of a vehicle's trajectory from all possible candidate trajectories using the license-plate-based AVI data on a large-scale urban road network. The destination choice model with pairwise district-level constants was proposed using the Quasi-Newton maximum likelihood estimates or the maximum likelihood estimates. On the contrary, the hierarchical Bayesian model was capable of estimating passenger-based OD flow matrices and the period-level OD flow matrix using the sampled OD flow data collected by cellular-phone-based AVI sensors and boarding data provided by passenger fare boxes. The iterative generalized least squares method has been proposed to estimate the mean and covariance matrix of OD demand with taking account the day-to-day variation induced by travelers' independent route choices using day-to-day travel time/speed data.

Optimization method: Similar to the earlier traffic-count-data-based models, the optimization method is still widely adopted for OD estimation with multiple sources of data. Researchers proposed various data-driven objective functions based on multiple sources of data in order to obtain the static and dynamic OD demands. Different from the traffic-count-data-based models, these models focus on the observed path (or) path segment flows and travel times, which provide more information for the OD demand estimation. The corresponding methods include least square method, itinerary-based nonlinear optimization model, sequential

updating method based on the maximum entropy principle, four-location models, heuristic expectation maximization method, bi-level programming model, etc.

Machine learning method: It was found in some recently developed OD estimation models that machine learning models were better at capturing the nonlinear relationships of available data as compared with the statistical models. The machine learning method is also less restrictive in terms of the assumptions regarding the error structures, making them arguably more appropriate for this application. The machine learning methods used in OD estimation includes K -nearest neighbors regression, support vector regression, neural networks: multilayer perceptron, ordinary least square regression, lasso regression, ridge regression, random forest regression, points of interest and K -means clustering method, etc. It was recently reported in the literature (Krishnakumari et al., 2019) that the multilayer perceptron, a neural networks approach, would lead to an outperforming model for the OD demand estimation purpose.

Remarks

This chapter discusses the comprehensive scope of OD estimation issues in order to provide a better understanding of the model development with different sources of traffic data and different modeling approaches. Although we have classified the existing models into different categories, some models may simultaneously belong to more than one category. For example, the maximum likelihood model utilizes both the statistical and optimization methods. In this chapter, we hope that the up-to-date review of the OD estimation models would be helpful for inspiring and stimulating new research initiatives to propose robust OD demand estimation models by adapting or developing innovative modeling approaches in the arena of Big Data.

Nowadays, due to the fast-growing development of traffic data collection technologies, OD estimation is increasingly convenient and more accurate as more traffic data can be available and used for OD estimation. In the age of Big Data, OD estimation studies will come into a new avenue with advanced and efficient technologies using multiple sources of different data (e.g., weather data) that are not restricted to the traffic-related data only.

The work described in this chapter was financially supported by grants from National Natural Science Foundation of China (Project Nos. 71671184 and 71271205), together with grants from the Research Grants Council of the Hong Kong Special Administrative Region, China (Project No. 152628/16E) and from the Research Committee of the Hong Kong Polytechnic University (Project No. 4-ZZFY).

Parking has become an increasingly serious problem in many large cities around the world because of the dramatic increase in the number of motorized vehicles. Traffic conditions have tended to deteriorate in many urban areas, particularly in densely populated development areas during peak periods. And hence, the time needed to search for parking has increased substantially in central business districts. An efficient parking demand management tool is required to improve the efficiency of urban transportation systems. This paper concerns the main aspects of parking demand study, including parking demand forecasting, parking behavior analysis, and parking demand management strategies.

The following parking statistics are important in parking demand research:

- *Parking accumulation* is defined as the number of vehicles parked at a given moment, which can be expressed by an accumulation curve (obtained by plotting the number of parking spaces occupied over time).
- *Average parking duration* is the ratio of the total parking time of the vehicles parked to the number of vehicles parked.
- *Parking turnover* is the ratio of the number of vehicles parked during a particular period to the number of parking bays available. For example, if a parking lot has 100 spaces and 300 different vehicles occupy the lot over the day, then the turnover is 3.0.
- *Parking occupancy* is the number of vehicles parked in a specific parking location, represented as the percentage of spaces occupied. The parking occupancy is an important index for the measurement of parking performance because it can help us understand the dynamics of parking demand during a day.
- *Parking occupancy rate* is the percentage of all parking spaces occupied by vehicles at a given time.

Parking Demand Forecasting Models

Advanced parking demand forecasting models are required to forecast the temporal and spatial distribution of future parking demand in a densely populated urban area. Reliable parking demand forecasting is the basis of efficient planning and management of a city's parking facilities. Overestimation of the parking demand inevitably results in a waste of funds and land resources devoted to parking facilities. Underestimation may lead to a severe shortage of parking spaces, which may restrict urban economic activities because of excessively long times needed to search for an available parking space in an urban area. Parking demand forecasting issues have recently attracted considerable attention because of their increasing importance particularly under the big data arena for smart parking demand management.

Parking demand forecasting usually adopts a combination of a disaggregate modeling approach and a regression approach, such as multiple linear regression. Such a combined method was successfully applied in a study of Hong Kong's parking demand by the Transport Department of Hong Kong in 1995 (Lam et al., 1998; Wong et al., 2000; Tong et al., 2004b).

In the disaggregate approach, the districts of the city concerned are divided into many zones, and each zone is further subdivided into many subzones according to land-use type (e.g., residential, institutional, business, industrial, agricultural, parkland). Parking activities are classified by various attributes, such as trip purpose (home-based work, home-based school, other home-based, nonhome-based, employer's business), parking space ownership (ownership-related, usage-related), vehicle type (private car, goods vehicle), and parking characteristics (on-street metered parking, on-street nonmetered parking, off-street parking, and illegal parking).

The multiple linear regression approach is used to estimate the demand for each parking activity in each zone. Such parking demand is related to various factors, such as demographic and socioeconomic characteristics, land-use patterns, vehicle ownership, parking supply, parking duration, parking turnover rate, parking searching time, and parking charges. The regression approach is used to reveal each factor's relationship with parking demand.

A city's population growth and socioeconomic development are closely related to its vehicle ownership and the trip frequency of its residents. As the level of socioeconomic development increases, the number of motorized vehicles and the frequency of their vehicle use increase, and parking demand thus increases with the level of demographic and socioeconomic development.

Land-use patterns show the use of the city's available land as dictated by urban and regional planners, including the land-use type and the development intensity of the unit land area. Urban land resources are usually allocated for the development of various functional facilities, such as commercial districts, schools, hospitals, and residential neighborhoods. The functional type of a zonal area determines its parking demand characteristics, including the number of trips generated or attracted, parking generation rate, parking duration, and parking accumulation. The intensity of land development also affects the parking demand in each zone. In general, the greater the intensity of the land development (or equivalently, the higher the floor area ratio), the greater the demand for parking in that area.

Vehicle ownership directly affects the implementation of trip activities and thus has an important influence on parking demand. Vehicle ownership is closely relevant to the supply of parking facilities. An increase in vehicle ownership usually requires the provision of more parking facilities in an urban area. It has been reported that the addition of a car to a city requires 1.2–1.5 additional parking spaces.

The parking turnover of a parking space is its rate of use. Turnover indicates how often a parking stall is used by different vehicles throughout the day. A higher average turnover rate is due to the fact of a shorter average parking duration. As a result, more vehicles can be parked and thus a higher parking service level, and the inverse is also true.

Parking search time is the time spent on looking for an available parking space. The parking search time, the walking time from the parking space to the final destination, and the parking charges affect a driver's choice of parking location and thus the distribution of parking demand.

Parking Behavior Analysis Models

Parking behavior analysis has great importance in exploring the spatial and temporal distribution of parking demand. The previous related models may be classified into two categories in terms of their objectives. One focuses only on the choice of parking location or lot (ignoring travel choice behavior on the road network) and the other considers the combined parking and travel choices. The former determines the parking location choice based on the parking facility's characteristics alone, whereas the latter aims to reveal the interaction between parking congestion and travel choices on the road network. In the following section, the factors that influence the choice of parking location are described, and the parking location choice models are introduced.

Factors That Influence Parking Location Choice

The characteristics or attributes of the parking locations greatly influence drivers' parking location choices. The parking location characteristics include the access time to the parking area, the parking charges, the hours of operation, the parking occupancy rate, and the walking time to the final destination. In a large central business district, a wide range of parking location types are available, including surface parking lots, multistory or underground garages, metered and unmetered on-street parking lots, and off-street parking locations.

Drivers' preferences for a parking location are also a significant factor. Drivers generally have preferences for their desired type of parking facilities and locations of parking lots. These preferences vary by the purpose of the trip, the drivers' perceptions of parking location characteristics, and inherent differences in their tastes and attitudes.

Parking cruising is another important factor (Shoup, 1999). When a driver arrives at a parking lot and finds that it is fully occupied, he or she must cruise to find the next parking lot. This phenomenon is quite common in daily life, especially during peak hours or at busy locations. Parking cruising has a significant effect on the search time for an available parking space and is a major contributor to road traffic congestion in the downtown areas of major cities.

Parking Location Choice Models That Do Not Consider Travel Choices

Discrete choice modeling is a popular method of modeling drivers' parking location choice behavior. In this family of models, various parking locations are considered as discrete alternatives. Drivers choose their parking locations according to the attributes of the parking alternatives and/or their preferences for parking locations under various behavioral decision rules. A multinomial logit model is usually used (Hess and Polak, 2004), which can also be extended as a nested or mixed type to consider correlations between the alternatives (Hunt and Teplý, 1993). The parameters in the multinomial logit model or its variations can be calibrated with various estimation methods (such as the maximum likelihood method or least-squares method) based on the stated preference and/or revealed preference survey data.

Integrated Models for Parking Location and Travel Choices

Parking is closely tied to road usage. The parking service level and parking policies affect not only drivers' parking location choices, but also their travel choices on the road network (e.g., route, departure time, and transport mode). One class of models integrates parking location and travel choices to consider the interaction between road traffic and parking congestion. Such integrated models usually adopt a network equilibrium modeling approach, which accounts for the demand–supply equilibrium of the parking services and travel choices (e.g., route, departure time, and mode choices) of the drivers on the network (Gur and Beimborn, 1984; Bifulco, 1993; Lam et al., 1999; Tong et al., 2004a; Lam et al., 2006). The generalized cost of a route–parking alternative from an origin to a destination consists of the following cost components: the in-vehicle travel time from the origin to the parking location, the search time for an available parking space, the parking charge, and the walking time from the parking location to the destination.

When making travel and parking choices, drivers consider the generalized costs of all route–parking alternatives between an origin–destination pair and choose one route–parking alternative with minimal generalized cost for the trip. When a user equilibrium state of the simultaneous route and parking location choice is achieved, for each origin–destination pair, the used route–parking alternative has the minimal generalized cost, and the generalized cost of any unused route–parking alternative is greater than or equal to the minimum. The static integrated model of parking location and travel choice can be extended to a dynamic version with the addition of a time dimension (e.g., departure time and parking duration).

Parking Demand Management Strategies

Parking demand management strategies include a number of policies and programs designed to reduce parking demand, preserve parking for certain trip types and users, and promote a shift from single-occupant vehicle trips to transit, pedestrian, and bicycling trips. These parking policies and programs offer a potentially strong instrument to influence road traffic flow and parking demand, including: (1) giving up on a trip plan because of heavy parking congestion, (2) changing the parking location or parking duration because of a parking time limit or high parking fee, (3) changing the trip destination because of parking control, (4) changing the travel mode (e.g., bus or rail), (5) changing the departure time (e.g., from peak period to off-peak period) or travel route, and (6) changing the trip frequency. Parking demand management strategies include parking pricing, supply-side strategies, and park-and-ride (P&R) schemes with an integrated multimodal service. Parking pricing involves the fee charged for parking, parking supply-side strategies involve restricting the supply of available parking spaces to achieve a desired objective, and P&R schemes involve an integrated service between multiple travel modes.

Parking Pricing

Parking pricing, or the fee charged for parking, is commonly used to control parking demand in busy parking lots during rush hours, including the application of on-street parking meters and pricing for garage parking (Anderson and de Palma, 2004; Van Ommeren and Russo, 2014; Qian and Rajagopal, 2015). The basic idea behind this policy is to control the spatial and temporal distribution of parking demand by properly setting parking rates to maintain an ideal level of parking occupancy such that any newly arriving drivers can always find a suitable open space without circling around.

Typical examples of parking pricing schemes include (1) differential pricing implemented over space and time, such as raising parking charges in areas with high parking demand (such as central business districts, employment areas) and during peak hours of parking demand (dynamic pricing responsive to the real-time parking occupancy level); (2) parking tariffs designed to discourage long-term parking and promote parking turnover (e.g., to prioritize parking for shopping customers rather than employees); (3) a downtown employee parking payroll tax; and (4) parking subsidies, including policies such as employer-paid parking, free shopping mall parking, parking coupons, and park-and-shop discount programs.

Rapid advances in information and communication technologies under the big data arena have allowed the use of intelligent parking systems to determine parking prices dynamically at various parking locations, leading to more efficient use of limited parking resources for smart parking demand management.

Parking Supply-Side Strategies

Parking supply-side strategies involve restricting the supply of available parking locations to achieve a desired level. Some typical strategies include (1) setting the maximum number of parking spaces and parking time limits (e.g., 2-hour maximum parking) for each zone (Arnott and Rowse, 2013); (2) designing parking permit programs in which only vehicles with permits are allowed to park in a parking permit area, such as residential parking and employer-provided parking (the distribution and trading of parking permits are important issues in this theme) (Zhang et al., 2011); (3) shared parking strategies, in which a parking space can serve two or more individuals at different times without conflict (an efficient shared parking scheme can significantly improve the usage rate of parking spaces) (Xu et al., 2016); (4) preferential parking for carpools or vanpools or alternative-energy vehicles; and (5) parking guidance systems, which guide drivers to the nearest available parking space by displaying real-time occupancy information.

Park-and-Ride Schemes

P&R schemes have been recognized as an effective means of addressing traffic congestion problems in densely developed urban areas (Lam et al., 2001; Wang et al., 2004; Li et al., 2007). These schemes encourage commuters to transfer from private cars to public transport modes to enter the city's central areas. Accordingly, the journey is divided into two parts: driving a private car to a car park near a transit station and making the remaining journey through public transit. Determining the optimal location and size of each P&R site is very important for successful implementation of these schemes. In practice, P&R sites are located at the periphery of built-up areas, near major radial road corridors and metro stations, and at or near the urban fringe.

P&R services can serve to supplement other transport policies, such as the restriction of parking supplies in urban central areas, increasing parking charges in central-area car parks, and the promotion of public transport, cycling, and walking. P&R schemes are becoming popular in some large Asian cities, such as Hong Kong, Beijing, and Shanghai, with the rapid development of metro systems.

Remark

This paper illustrates the wide scope of parking issues in order to achieve a better understanding of parking demand and its impacts on urban traffic conditions. Apart from providing timely reviews of recent methodological advances on various parking issues, we hope that this paper will inspire and stimulate new research initiatives and efforts in the application of various parking demand models, parking behavior analysis methods, intelligent parking systems, and parking demand management strategies for the design of more efficient and reliable transportation networks in future.

Importance

The 2016 American Infrastructure Report Card from the American Society of Civil Engineers gave D+ grade for America's infrastructure and estimates a 1.1 trillion USD funding gap on surface transportation investment (ASCE, 2016). This highlights the urgent responsibility that highway agencies face to develop strategies to achieve and maintain their assets in a state of good repair at minimum practical cost over the life cycle. At the same time, agencies are also facing severe funding shortfalls due to gas tax and other revenues that is not keeping pace with the growth vehicle miles traveled and inflation that require them to establish performance-based metrics to defend funding requests and provide accountability. Implementation of a systematic and strategic approach of managing pavements using a PMS can lead to improved network condition (Fig. 1), a higher level of service to the public, a better understanding of trade-off analysis between different assets, and a more streamlined decision process. While a PMS cannot make final decisions, it can provide the basis for an informed decision and possible consequences of alternative strategies (AASHTO, 2012). Many transportation agencies are also developing integrated approaches for making investment decisions that consider impacts on multiple assets. In the United States for example, recent law requires States to develop Transportation Asset Management Plans (TAMP) that act as a focal point for information about the assets, their management strategies, long-term expenditure forecasts, and business management processes. TAMPs are essential management tools that bring together all related business processes and stakeholders to achieve a common understanding and commitment to improve performance.

Pavement Management Approaches

Pavement management supports agencies decision at three levels: strategic, network (tactical), and project (operational). Strategic decisions are made at the upper management level within the agency by staffs responsible for making policy and investment

Figure 1 Trends in poor and good pavement condition in Washington State highways following adaptation of a pavement condition survey in 1969 and a pavement management system in 1982 (FHWA, 2010a). Source: Washington State Department of Transportation Materials Lab.

decisions, such as elected officials, transportation boards and commissions, and city councils. The task at this level is to make long-term strategic decisions that reflect agency priorities and setting performance targets. The decisions at this level are generally less structured than decisions made at other levels.

Network-level decisions are concerned with achieving agency goals for an entire road network through multiyear improvement programs. These decisions include: establishing pavement preservation policies, identifying priorities, developing recommended list of maintenance, rehabilitation, and reconstruction (MR&R) treatment type, location and timing over the multiyear analysis horizon and estimating corresponding funding needs, and allocating budgets based on prioritization that meets the agency policies and priorities. The results of the network-level analysis are used in strategic level to set realistic performance targets and to evaluate investment options. Project-level decisions address selection of site-specific MR&R actions for individual projects and groups of projects based on site-specific conditions. For instance, cores and material testing may be conducted to determine in situ structural conditions at project level, but an indirect nondestructive testing is usually used at network level.

Components of Pavement Management System

The basic component of pavement management system (PMS) includes inputs, database, analysis components and modules, reporting module, and feedback loop. The features of each component vary with individual agencies requirement and the subsequent section provides a general overview of each component.

Data Collection

The data upon which all decisions are made form the basis for any PMS. The quality of decisions is largely function of the data available to support those decisions. Inputs include information on inventory, pavement condition, age of last and/or previous treatments, and traffic counts. The information needed are often collected or maintained by different divisions of the agencies. Traffic or planning division staff are responsible for traffic data while construction and maintenance staff are responsible for maintenance and rehabilitation history of the pavements.

Inventory Information

The level of detail per section depends on each agency's goals and methodology to support their decision. A typical inventory feature of the pavement segment includes start and end reference point and/or global positioning system (GPS) coordinates, route designation along with route type, functional classification, segment length, width and type of pavement and shoulder, number of lanes in each traffic direction, construction history (year, treatment type, layer(s) type, material properties, and layer(s) thicknesses), subgrade type, and climate and traffic information. In addition, for jointed plain concrete pavements, joint spacing and transverse joint load transfer are also included when possible.

Pavement Condition Evaluation

Pavement condition evaluation is a key element of pavement management. Systematic and regular pavement condition evaluation provides the data an agency needs to make informed decisions on treatment type, location and timing for the efficient management

Table 1 Pavement distresses (FHWA, 2004)

<i>Pavement</i>	<i>Hot mix asphalt</i>	<i>Jointed plain and jointed reinforced</i>	<i>Continuously reinforced</i>	<i>Composite</i>
States reporting	50	47	21	41
Roughness	98%	100%	100%	100%
Rutting	100%	N/A	N/A	N/A
Fatigue or alligator cracking	96%	N/A	N/A	N/A
Longitudinal cracking	86%	81%	90%	100%
Transverse cracking	94%	83%	N/A	100%
Transverse joint faulting	N/A	74%	N/A	N/A
Transverse joint spalling	N/A	74%	N/A	N/A
Punch-outs	N/A	N/A	86%	N/A
Surface friction	68%	66%	81%	68%
Other	46%	47%	57%	61%

of the network, report current pavement condition, assess past, and forecast future performance. Network-level pavement condition evaluations are conducted on a 1–3-year cycle based on agency policies, legislative requirements, and highway classification. The type of pavement condition data normally collected by transportation agencies can be generally fit into three categories:

1. **Surface distresses:** Characterizing visible condition along the pavement surface can provide direct indication of the performance problem and thereby helpful in selecting suitable treatment and planning long-term strategies. The cause can be either traffic load or non-traffic load related. The distresses are categorized by pavement type and rated by severity (e.g., [WSDOT, 1992](#)). The common distresses collected in the United States are presented in [Table 1](#). The other widely used guide to define pavement distresses is ASTM D6433, Standard Practice for Roads and Parking Lots Pavement Condition Index Surveys. Distress surveys can be manual or automated. Manual surveys are visual assessments of field conditions conducted through the windshield of a vehicle or by walk along the section. Automated surveys are conducted using instrumented vehicles and then computers are used in data processing to extract distress information with little or no human intervention (NCHRP Synthesis 334) ([National Academies of Sciences, Engineering, and Medicine, 2004](#)).
2. **Surface characteristics:** This involves measured surface smoothness (longitudinal profile, surface texture) and noise. Longitudinal profile is typically reported using International Roughness Index (IRI), an index originally developed by World Bank for use in Highway Development Model. Present serviceability index (PSI) is another index commonly used to characterize roughness and distresses. Surface texture is subdivided into three distinct groupings by their wavelength and amplitude: microtexture, macrotexture, and megatexture. The microtexture and macrotexture influence pavement's wet weather friction characteristics and hydroplaning potential. Noise is still not mostly collected on routine basis.
3. **Structural capacity:** Functional condition is not necessarily linked to structural condition. Structural evaluation estimates the adequacy of an existing pavement to meet future traffic loadings. Destructive testing such as coring and nondestructive testing such as pavement deflection devices are the common methods to estimate structural adequacy. Falling weight deflectometer (FWD) is the most commonly used device to assess pavement responses. The structural evaluation is typically conducted at project-level investigation due to the limitation of technology to conduct network-level investigation. However, the latest advancement in traffic speed deflection device technology has enabled deflection measurement at network level without the necessity of traffic control for testing. Traffic speed deflectometer and RAPTOR are the two commercially available devices for network-level pavement structural evaluation.

Traffic Counts

Past and projected traffic volumes and loads are critical in making both network- and project-level pavement management decisions. Traffic monitoring guide ([FHWA, 2001](#)) provides a basic traffic data collection framework for agencies. Automated and manual are two general methods of traffic data collection. A weigh-in-motion (WIM) detector is the common automated device used to measure dynamic tire forces of a moving vehicle and estimates corresponding static tire loads. Manual method refers to visually observing number of vehicles and classification, vehicle occupancy, turning movement counts, or direction of traffic using tally sheets or electronic counting boards.

Data Management

Design, construction, rehabilitation, and maintenance information used with in pavement management are often drawn from different sections within an agency. Location referencing system (LRS) is the foundation of a road data management system and hence the key to data integration. A LRS contains multiple location reference methods, each referring assets and/or attributes for a single asset within their reference framework. For pavement management, data can be referenced using linear features, point features, or a combination of the two. For example, smoothness data (IRI) are based on fixed linear segments, while friction data or FWD are based on point data. Geographic information system (GIS) containing spatial and attribute data is used for storing, managing, retrieving, querying, analyzing, and presenting data.

Figure 2 Sample decision tree (FHWA, 2008).

Performance Modeling and Prediction

The treatment and project selection methodology involve pavement deterioration models, treatment rules, and cost model. In an ideal case, the effect of any treatment should be mechanistically evaluated considering current pavement condition and future traffic loading and climate in determining the treatment type and timing for any pavement section to minimize long-term or life-cycle cost. However, current pavement deterioration models are largely empirical and the agency develops decision tree/matrix (Fig. 2) based on experience with treatment types and their performance when applied to pavements at different conditions. The decision tree includes performance models, treatment trigger rules, and impact rules or reset values that define the jump in pavement condition after each treatment application. The treatment costs are also required in estimating budget needs.

Engineering and Economic Analysis

Depending on the technical and business requirements and policy of the agency, the analysis may involve identification of projects and treatments, and consequence of different investment levels. Most agencies employ proactive pavement preservation activities to thriftilly extent pavement service life. Under fiscal constrained analysis, approaches such as ranking, prioritization, or optimization are used in project selection at single- or multiyear analyses. Life-cycle cost analysis (LCCA) is common method of comparing the

cost-effectiveness of a number of different strategies over a multiyear analysis period. This module also estimates future network condition for different investment levels that would be instructive in planning and reporting to elected officials.

Reporting and Feedback

Stakeholders use pavement management information for various purposes. Conventional reports are the common method of distributing information after completion of each round of condition surveys. Agencies use GIS-based tools or web-based programs to access and view pavement management information. Graphics are usually used to communicate the primary message quickly and effectively.

Feedback loop is a critical step in keeping PMS abreast. Updates shall include changes in pavement performance or conditions under which treatments are used, or changes in material properties or construction. Ideal scenario would be to create a feedback mechanism between pavement designs and observed performance that will lead to more cost-effective pavement designs.

Future Directions

Pavement management continues to evolve to meet progressive goals of the agencies. In 2010, FHWA sponsored the development of pavement management road map to identify steps needed to address current gaps in pavement management ([FHWA, 2010b](#)). Short- and long-term needs are grouped under the use of existing technology and tools, institutional and organizational issues, broad role of pavement management, and new tools, methodologies, and technologies. In addition, the following topics are identified as some of the ongoing researches to better serve the progressive goals.

Closing the Gap Between Pavement Design and Pavement Management for Better Pavements

PMS concept was conceived as framework for pavement design (project level) but has since evolved, and in many cases disassociated from pavement design, as a system to optimally manage and maintain pavements (network level). Contributing to this divergence were the different performance indicators used for pavement design in previous design procedures and pavement management. Development of the current mechanistic-empirical-based pavement design procedure based on similar performance indicators as that used for pavement management has brought to forefront the need and the benefits of relinking pavement design and pavement management. Pavement design and management share many features and can be the feedback loop for each other. For instance, integration of pavement design inputs into pavement management can lead to better performance prediction, while past performance in the management can be used to arrive at better design. Calibration/validation can be done ad hoc. Spatial variability on each pavement section and the variability among pavement sections with similar traffic-climate-materials can be used in transforming deterministic performance prediction models into probabilistic models. Closing the gap would reconcile the maintenance and rehabilitation (M&R) treatments regime that is derived from LCCA during project-level design with the M&R regime that is the result of optimal budget allocation during network-level PMS.

Technology

In recent years, significant improvement has been made in data collection technology. Automated pavement condition surveys are more efficient and safer than manual surveys. The laser crack measurement system (LCMS) is one of the recent, high-performing, and accurate technology available commercially for pavement crack detection. Continuous friction measurement equipment (CFME) such as the Sideway-Force Coefficient Routine Investigation Machine (SCRIM) and proactive pavement friction management programs are being developed to significantly reduce the number and severity of crashes by decreasing pavement friction and texture-related crashes.

Integrated units are currently available that can collect at highway speeds the pavement surface distress and structural data as well as other characteristics such as transverse profile/rutting, grade, cross-slope, pavement texture, GPS coordinates, right-of-way video, and pavement video.

With advancement in vehicle automation technology comes the challenge of understanding its impacts on roadway infrastructure. The connected vehicle and truck platooning that might reduce wheel wander and spacing between trucks thus increasing concentrated wheel loads and reducing pavement relaxation time are currently being investigated to understand their effect on pavement performance.

Evolution of Transportation Asset Management (TAM)

TAM is a process that enables agencies to use engineering and business practices to make more informed and transparent investment decisions. Several processes are required for successful TAM practices, including effective decision analysis methodologies that are informed by quality data and performance measures. The interaction between models, data, and performance measures is a critical one for the success of TAM implementation. There is a focus on incorporating cross-asset and trade-off analysis in management

systems that can be beneficial for coordinating total highway programs, determining performance measure targets, and allocating funding among different asset classes.

There is international effort on use of forward-looking metrics that measure the sustainability of infrastructure conditions. These metrics encourage a long-term, asset-management-based approach to managing infrastructure, not just to meet condition targets today, but also to sustain those targets into the future. Asset Sustainability Index is one such composite metric computed by dividing the amount budgeted on infrastructure maintenance and preservation over time by the amount needed to achieve a specific infrastructure condition target.

Performance Management and Accountability

Performance-based management program allows stakeholders to invest resources in projects that collectively will make progress toward the achievement of its strategic goals. For example, a new rule enacted in the United States, Moving Ahead for Progress in the 21st century (MAP-21) Act, is about establishment of a performance- and outcome-based program (MAP-21, 2012). The rule set national performance goals for federal-aid highway program in seven areas: safety, infrastructure condition, congestion reduction, system reliability, freight movement and economic vitality, environmental sustainability, and reduced project delivery delays. New performance measures are being established to quantify the new and changing agency goals and objectives and to set performance targets.

FHWA strategic plan for FY 2019-22 set safety, infrastructure, innovation, and accountability as the four strategic goals. There is increased effort to improve program and project decision-making by using a data-driven approach, asset management principles, and a performance-based program that will lead to better conditions and more efficient operations.

Life-Cycle Planning (LCP)

LCP is an approach to manage transportation assets over their whole life, covering the time each asset goes into service after construction to the time it is retired or disposed of. The Asset Management Rule (See 81 Federal Register 73196) by US DOT emphasizes the importance of LCP in its definition for asset management, as shown later: *A strategic and systematic process of operating, maintaining, and improving physical assets, with a focus on both engineering and economic analysis based on quality information, to identify a structured sequence of maintenance, preservation, repair, rehabilitation, and replacement actions that will achieve and sustain a desired state of good repair over the life cycle of the assets at a minimum practical cost.*

The rule defines LCP as “a process to estimate the cost of managing an asset class, or asset sub-group, over its whole life with consideration for minimizing cost while preserving or improving the condition.” LCP should not be confused with LCCA at the project level. An LCCA considers all agency expenditures and user costs throughout the life of strategy. LCP is a network-level analysis that encompasses many aspects of an engineering economic analysis, including opportunity cost, noneconomic factors, and funding constraints (FHWA, 2017). Remaining service interval (RSI) is one such performance measure that can unify the outcome of different life-cycle approaches to determine needs by focusing on when and what treatments are needed while maintaining the service level (Elkins et al., 2013).

Incorporation of Sustainability and Risk

Sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs. Agencies strive to improve the triple bottom line (social, economic, and environmental factors) over the life cycle of an asset through life-cycle assessment (LCA). The economic component has been the dominant decision factor for many years, but recent years have seen the emergence of both the environmental and social components. Though all triple-bottom-line components are considered important, but the relative importance of these factors and how each are considered are driven by the goals, demands, characteristics, and constraints of a given project (Van Dam et al., 2015). Current research focuses on developing comprehensive LCA tool based on systematic framework, compiling unbiased database, product category rule for common materials, and quantifying contribution from different phases of the pavements including construction, maintenance, and use phase.

Risk assessment involves identifying and evaluating sources of risk and developing mitigation strategies. MAP-21 Act adopted a requirement for States to develop and implement risk-based asset management plans for the National Highway System to improve or preserve the condition of the assets and the performance of the system.

The infrastructure should be resilient to extreme weather, sea-level change, and changes in environmental conditions to preserve the considerable investment. Resilience as defined by FHWA is *the ability to anticipate, prepare for, and adapt to changing conditions and withstand, respond to, and recover rapidly from disruptions*. The Fixing America's Surface Transportation (FAST) Act in the United States requires agencies to take resiliency into consideration during transportation planning processes (FAST Act, 2015). US Department of Transportation Strategic Plan for FY 2018-2022 includes development of new tools to improve transportation infrastructure durability and resilience as a priority innovation area (Dix et al., 2018). The stakeholders have started working on assessing vulnerabilities, incorporate resilience in asset management plans, addressing resilience in project development and design, and optimizing operations and maintenance practices.

Biography

Senthilmurugan Thyagarajan is a Research Civil Engineer, ESC Inc., working at Turner-Fairbank Highway Research Center, McLean, Virginia, for over 10 years. His areas of interest include pavement design, pavement performance modeling, pavement structural evaluation, life-cycle cost analysis, life-cycle assessment, and pavement management-related topics. He has obtained his Bachelor's degree in Civil Engineering from Madurai Kamaraj University, India, and a Master's degree in Soil and Foundation Engineering from Anna University, India, and PhD in Civil Engineering from Washington State University, United States. He is licensed professional engineer in the state of Maryland and Virginia, USA.

Introduction

Being a cornerstone of spatiotemporal urban processes in the modern era, residential choice has been a focus of interest for urban planners, economists, and transport planners alike for almost 50 years. Residential choice can be viewed from the real-estate market perspective, the urban growth and development perspective, and the urban flow perspective. *Looking through the lens of the real-estate market*, residential choice serves to understand spatiotemporal dynamics, consumer preferences, and constraints. Unlike other consumer goods, buildings are durable assets that have an exceptionally long-lasting life span from decades to centuries, meaning that the current generation housing supply and the nature of the built environment is a mediator between past and future generations. Moreover, residential choice is the most important determinant of land consumption, defining the depletion of regional and national land resources. Further, a mismatch between housing supply and demand leads to surges of spontaneous, informal housing markets consisting of poorly built unsafe housing structures causing environmental, health, and life concerns. *From the regional development perspective*, residential housing markets represent bottom-up and middle-out market forces that create pressure for land-use development and top-down policy implementation. From the traditional policy and practice perspective, residential choice can determine the long-term success or demise of regional ventures, and the four stages of regional development: urbanization, expansion, growth, and decline and revitalization. Residential location choice helps to explain processes driving regional development such as inter- and intra-urban migration, suburbanization, segregation, ghost apartments and towns, labor market success and failure, recovery from natural hazards, and urban resilience. Therefore, understanding residential choice is a basic unit of analysis in regional master plans as well as in disaster management and increasing urban resilience. *From the urban flow perspective*, residential location choice affects the individual space–time prism in and is closely tied to lifestyle choices of land consumption, workplace, car ownership, modal choice, activity participation and travel patterns, as well as long-term life opportunities. Thus, residential choice drives the daily rhythms and flows of urban transport and activity patterns that allow planners to plan efficient, economic and sustainable transport, urban functions, and other vital infrastructures. Accordingly, residential choice is a basic building block in traditional four-stage transport models as well as the most advanced state-of-the-art agent-based urban development models, activity-based, urban transport models, as well as combined dynamic transport and land-use models.

Theoretical Foundation

The representation of residential choice in regional science was theorized in William Alonso's bid-rent theory (Alonso, 1964). The theory postulates households competing on land plots in a monocentric city, trading off distance from the city center with land-plot size. According to the theory assumptions, location matters with accessibility to the central business district (CBD) and main city function is the most attractive feature of urban location. However, households are willing to trade their accessibility to the CBD with a larger amount of land consumed. The theory produces a theoretical bid-rent curve with higher values near the CBD and lower values near the city outskirts. The theory established the two main factors in residential choice—the relative location from resources and the amount of land consumed. The theory explains residential, firm, and retail location. The theory was developed in the 1960s and its basic dynamics stem from agriculture and medieval city structure, but its rigorous economic principles hold for today's

modern cities. Nevertheless, the theory has undergone updates and amendments due to the growing complexity in urban form, and gained knowledge of human choice dynamics and the growing need to increase behavioral realism and modeling goodness-of-fit. Modern-day urban environments are multicentric and more complex and dispersed with declining and resurging trending urban locations, variety of housing types, and policy measures such as zoning and urban growth boundaries, which alter land-use dynamics. Yet, recent research of real-estate databases from the United States shows that the bid-rent curve holds at the local level when considering polycentrism and transportation infrastructure resulting in travel time as a distance measure. Starting from the 1970s, the bid-rent theory has led to the evolution of two separate research branches, which act as two-sided coin. The first branch takes the supply-side perspective by focusing on hedonic evaluation of dwelling units and land-use parcels for development. The second branch takes the demand perspective by looking at residential choice from a utilitarian perspective following the principles of microeconomics. The move to utility-based models in the 1970s was mainly driven by the need to develop and implement urban simulation models that represent the interaction between residential markets, labor markets, and transportation interact. Half a century later, in current agent-based models of urban development, which simulate urban development processes based on a utility-based development probability of land-use parcels, the two branches coincide to represent urban dynamics overtime.

Empirical Choice Modeling

Residential choice is one of the most complex choices in terms of its mathematical representation, due to three reasons. Hence, from the 1970s residential location choice has been extensively modeled both in transportation and regional science. The complexity is fourfold. First, location choice is characterized by an immense number of viable alternatives, considering both location and dwelling unit type. A metropolitan scale considering only location, the number of alternative zones as units of analysis could range from several hundred to over a thousand alternatives. When considering precise location and dwelling unit characteristics, the numbers become inflated and the choice problem could become unmanageable. Moreover, the choice is conducted under partial information, thus violating the assumption of full information embedded in the utilitarian approach. Second, residential choice is naturally highly influenced by population heterogeneity as a result of its importance, long-term impact, and high costs. Thus, in addition to mere socioeconomic background and constraints, the choice is influenced by individual life stage, lifestyle, attitudes toward housing, personal values, and norms. Third, location choice alternatives are spatially correlated because of geographical proximity, construction style similarities, location amenities, and sociodemographic characteristics. Last, while housing rental choices are conducted a few times in a lifetime, housing purchase and sales are rare events in the life of the individual and thus are difficult to trace. Because of these reasons residential choice is an elusive process, which is difficult to estimate and predict with high accuracy. Bearing this in mind, starting from Daniel McFadden's nested logit model (McFadden, 1978), the research efforts identifying and addressing the complexities embedded in residential choice helped gaining new insights and pushed forward advancements in econometric models. Since the 1970s, the use of probabilistic discrete choice models gradually became a main research tool exploring a wide range of aspects in residential choice. Due to the wide scope of residential choice and its interdisciplinary nature, encompassing and charting the full extent of current practice is essential for envisioning and undertaking new research directions. The following subsections describe the state of the practice in discrete choice modeling of residential decisions from several perspectives: definition of the residential choice bundle as the dependent variable, investigated themes, decision strategies, choice set formation, and model form and survey methods.

Defining the Residential Choice Outcome and Choice Set Formation

The choice of a dwelling unit as a bundle of attributes is inherently complex due to the multi-attribute nature of housing. Each dwelling unit is characterized by numerous attributes including geographical location, public services, social and environmental amenities, education (school) quality, accessibility, external and internal structural features and costs. However, true to the old saying that "location, location and location are the three most important factors in the real-estate market," the residential choice literature focused mainly on location and related amenities. A wide range of location variables were represented: size and density of areas, population characteristics and employment levels, land-use destinations, accessibility measures, commute and travel information, local transportation network, environmental amenities, social amenities, local public goods and services, and average housing costs. About 25% of the studies consider residential choice as a bundle of location-related features and dwelling unit characteristics, while less than 20% focused only on dwelling unit features. The dwelling attributes that were considered are costs, tenure, structural features (e.g., size, number of rooms, direction, and floor), appliances, and utilities. While most studies focused on residential choice as a single decision, some studies divide it into a series of correlated choices differentiating the decision to stay or move, the choice of tenure type, location choice, and dwelling type.

Since the compensatory approach assumes a choice from a given and well-specified choice set, the main approach for choice set formation requires defining the choice set prior to the model estimation either by application of deterministic availability rules, aggregation of alternatives, or sampling from the universal realm. Deterministic availability rules in the residential choice literature consisted usually of spatial constraints that were applied to the whole sample. Namely, the analysis was confined to one or more well-defined spatial units, such as county, city, community, or metropolitan area. Deterministic availability constraints were also applied per observation on the basis of travel time and housing affordability. Aggregation applied to residential choice concerned mainly housing market sectors by building type, tenure, size, or quality. Another aggregation method concerned spatial units by

proximity or by similarity. Sampling methods applied to residential choice comprised mainly stratified and non-stratified random sampling (Lee and Waddell, 2010). In terms of choice set-size, the literature shows great variation with the number of alternatives spanning from several alternatives in the early modeling stages to several hundred alternatives with more recent modeling capabilities.

Joint Choices

Understanding urban equilibrium of residential markets, labor markets, and transportation has largely driven the need for joint modeling of residential location choice and other lifestyle decisions. The earliest examples of joint decisions, already in the beginning of the 1980s, are an integrated choice of residential location choice and travel mode and a simultaneous decision of residential and workplace location choice. Today, there is also a growing tendency to jointly model residential location choice with several other lifestyle decisions with the most commonly modeled joint decisions are coupling residential location with workplace location, car/bicycle ownership, activity patterns, and transport mode. An example of a model integrating six lifestyle dimensions is a model incorporating residential location choice, work location choice, automobile ownership, commuting distance, commute mode, and number of stops on commute tours. These joint choices are typically represented as hierarchical choice processes, which carry both the problem of the defining the choice order, which can be solved by means of latent market segmentation which respect to the choice structure, and a rapidly increasing realm of possible choices, in particular in the case of residential and workplace choices.

Population Strata

The majority of the studies that focused on population groups covered differences among groups. The differentiation among groups was conducted according to income and number of employees in the household, ethnicity, and gender. A few studies concentrated on residential choice of specific groups, particularly elderly, youth migrating from rural to urban areas, dual-earner households, students, and high-skill knowledge-workers.

The main population strata of interest from the 1980s until the beginning of the new millennium were mainly the move from the traditional bread-winner housekeeper household type to dual-earner households, and the role of job perks and the ability to telecommute on residential mobility and location decisions of the household. More recently, research in this direction has taken a turn toward understanding self-selection processes guiding joint residential and lifestyle choices. In the 1970s, researchers were mainly concerned with spatial segregation on the basis of ethnicity and socioeconomic status and the impact of such segregation on equity. Nowadays, while equity is still an important issue, the main discussion is voluntary self-selection in correlation with other lifestyle choices. For planners, understanding residential self-selection is important for improving the representation of the household characteristics in activity-based models and integrated transport and land-use models. For policy-makers, self-selection may lead to voluntary segregation and generate spatial and intergenerational inequities. From the beginning of the millennium, the growing role of education in the economic basis of regions and cities and the positive role of students as revitalization catalyzers versus the negative externalities of large masses of students in medium-sized cities (i.e., studentification) have motivated research toward understanding the residential choice of students in local housing markets. Richard Florida's theorem of learning regions sparked interest in migration of knowledge-workers as a growth engine for knowledge-cities (Florida, 2002). Following Florida's theorem that knowledge-workers are characterized by high residential mobility and high sensitivity to lifestyle, new research has surged to understand international and regional migration of knowledge-workers as well as their intra-metropolitan location choices. This research stream is closely tied to innovation and regional development, with the main aim of understanding the attraction and retention of young, highly skilled knowledge-workers. This research line is important also because it is deviating from the traditional view of a tight knit between residential location and job opportunities toward a more sustainable approach considering also social and environmental perspective. It has also contributed to extending the definition of urban amenities from "hard" physical amenities to "soft" cultural amenities and has highlighted the role of otherwise neglected city features such as nightlife, street art, street ambience, architecture, walk ability, green scenery, and sport amenities.

Decision-Makers

Households are the most common decision-maker unit in transportation. Namely, the main assumption is that the household can be regarded as a non-separable unit with a single utility function. This representation is based on the assumption that once negotiations end, the household can reach an agreement regarding the desired location choice and that the selected choice largely reflects a consensus. It is also based on the assumption that the household has a single utility function upon which all members agree. While this could fit to some extent traditional breadwinner-housekeeper households, this assumption loses its validity in two-earner households and power couples as well as with the growing role of childcare and education. Starting from the end of the 1990s, the commuting needs of two-earner households were incorporated both into the theoretical specification of the household location geometry and into the utility function. The new perspective of household no longer views the household as an integral unit but rather as a group of individuals with different objectives that could vary in their degree of conformity. This perspective is particularly important in the joint modeling of residential location and lifestyle, because household members can significantly vary in their

lifestyle choices. Therefore, the household unit is now viewed as a group of decision-makers that needs to negotiate their interests. Thus, instead of a single utility function, a conjoint analysis of preferences and group dynamics are explored.

Decision Rules and Model Form

The models applied to residential choice can be classified according to their underlying choice strategy, choice set formation process, and model form. As a general rule, residential choice models follow the utilitarian approach and assume a compensatory choice process guided by the principle of additive utility. This approach carries important advantages with respect to the mathematical representation of residential choice: ease of estimation, reproduction of market shares, ability to account for spatial correlation patterns and population heterogeneity, ability to model jointly correlated choices, and the possibility of model estimation from standard data collected by municipal and government authorities.

Among the estimated models, the most prominent one is the multinomial logit (MNL). Roughly one-third of the studies attempted to resolve the constraints of the MNL: independence of irrelevant alternatives, population homogeneity and homoscedasticity. To resolve the first constraint, the estimation of the Nested Logit is the most popular approach, but other Generalized Extreme Value models have also been estimated, with the most advanced being the Spatially Correlated Logit (Bhat and Guo, 2004) and the Generalized Spatially Correlated Logit (Sener et al., 2011). The second constraint of population preference homogeneity was resolved with various application of mixed logit with random coefficients, and both constraints have been resolved with mixed versions of the Generalized Spatially Correlated Logit. Joint choice models are estimated as means to address residential choice and other lifestyle decisions that guide residential self-selection. This line of models started by combining the MNL with ordered response models (MNL-OR) for modeling the combination of residential location and car ownership and continues with a series of models combining the MNL with Discrete-Continuous Extreme Value (MDCEV) models for representing the joint decision of residential choice, car ownership, activity, and time use patterns.

Only a few studies addressed non-compensatory decision rules, although research efforts steadily continued from the 1980s and until this decade. This approach stems from the bounded rationality approach criticizing the assumptions of full information and the ability to even proximally calculate the utility of alternatives deriving from a large choice sets. Due to the complexity embedded in the efficient estimation of non-compensatory and two-stage models, as well as the intensive data requirements, this line of research is slowly advancing. The first non-compensatory model to be applied to residential choice is the Elimination-By-Aspects model, which was applied to an example of three alternatives, because of the model limitation in handling large choice sets. Other studies estimated two-stage semi-compensatory choice models, which combine probabilistic choice set formation based on random thresholds followed by an MNL model based on Manski's approach of jointly estimating the probability to choose a choice set, and the probability of an alternative to be chosen from the choice set. The models' main focus is the representation of threshold selection as a function of individual characteristics and jointly accounting for the selection of multiple thresholds, both of continuous and discrete nature. The focus on choice set selection has started with socioeconomic constraints to account for threshold selection of location characteristics such as dwelling unit price, attributes, and proximity measures. Starting from 2015, the focus is shifting toward understanding the role of lifestyle, attitudes, and norms in the specification of threshold selection, with the corresponding model structure being the generalized heterogeneous data model (GHDM) combining latent variables underlying the joint choice of multiple thresholds from various types. The modeling advantages and the superiority of the mathematical representation of choice set formation and threshold selection in residential choice compared to the traditional models that assume a single unified choice set have been consistently proven using various data sources.

Data Sources for Estimation

The vast majority of residential choice models have been estimated by using revealed-preference (RP) data with a limited number of studies using the stated-preference (SP) or the combined RP-SP approach. The advantage of RP surveys is that they reflect actual choices in real-world situations. However, RP surveys are subject to two disadvantages when applied to residential choice. The first disadvantage lies in the difficulty to observe revealed residential choice preferences at the point of decision, since residential choice decisions are infrequently made during the average household life cycle and the residential decision process may span over long periods (from several weeks to several years). The second disadvantage consists in the limited ability to represent trade-offs among attributes, since RP surveys are limited to existing residential choice bundles and thus may not adequately represent the full range of attribute values. The advantage of SP surveys is the relative ease of data collection during the choice task and the possibility to control the range of attribute values. However, their disadvantage in the context of residential choice is that they are subject to hypothetical response bias, since individuals do not bear the consequences of their chosen alternative. Early research efforts involved mainly recruiting current home buyers/renters or households who have recently moved, for example, through newly built neighborhoods and real-estate agents. Existing data sources that are commonly used for residential choice model estimation are census data, national travel habit surveys, economic data sources, and regional or national housing surveys. An example is the American Housing Survey (AHS), sponsored by the Department of Housing and Urban Development. Because of the difficulty of observing revealed residential choice preferences at the point of decision, most of the studies consider the actual place residence at the time of the analysis. These data sources are mostly employed for cross-sectional analysis or pooled panel data, thus ignoring the time dimension. Moreover, households choose residences at different time points, so the same location may change over time. The disadvantage of this approach is that changes in environmental and societal conditions between the time of the decision and the

time of the analysis are not accounted for. Approximating the choice at the point of the decision can be done by restricting the analysis to choices of recent movers or new residents or alternatively referring to moving status.

Implementation in Transport Models

Residential choice models are not an integral part of traditional four-stage transportation models. In four-stage models, the location of the households is predetermined according to population forecasts on the basis of socioeconomic trends. In four-stage transport models, the data units of analysis are traffic analysis zones. In contrast, residential choice models are a key component in agent-based activity-based models and in integrated dynamic land-use and transportation models. In agent-based models, the unit of analysis comprises individual agents representing individual decision-makers. Synthetic populations representing current and future generations are compiled, consisting of attributing socioeconomic characteristics, residential location, car ownership, and activity patterns to each agent. The travel choices of each agent are derived from its inherent characteristics. While the generated synthetic population follows predetermined population distributions, unlike trend forecasting, the synthetic population is simulated at the individual level. The joint estimation of residential choice, car ownership, activity, and time use is a primary requisite for modeling derived travel demand. When short-term simulation is performed, residential choice is employed only to define the preconditions of the synthetic population. When long-term simulation is performed, integrated land-use and transport dynamics take place, through the iterative change of residential choice, job location and travel choices, their evaluation, and reassessment. The long-term integrated land-use and transportation approach allows understanding codependencies between transport and land-use development, understanding housing price fluctuations, and predicting urban processes of expansion, deterioration, and renewal.

Further Research

Online sources for modeling residential choices: RP residential choice studies did not manage to observe residential choice at the point of purchase/rent decision. The majority of the studies referred to the actual residence at the time of the analysis as the choice at the decision point. Such an analysis is retrospective and susceptible to unknown changes in the location specification of each household. Moreover, the choice set used at the time of the decision is unknown to the researchers. With the advancement of online real-estate databases, public access to real-estate transaction records, and computer-based databases of real-estate agents, analysis of real-estate transactions at the time of the decision is becoming a realistic option, which will vastly improve the representation of residential choice processes.

Lifestyle, hedonism, attitudes, and norms: Residential choice has been explained mostly from the functional gain (utilitarian) perspective. However, lifestyle, attitudes, and norms, as well as normative versus hedonic goal framing, are latent constructs that motivate housing choice and their affect can interact or override pragmatist housing choice. Lifestyle components represented by the individual's activity pattern are known to be correlated with residential choice. Both green attitudes and luxurious lifestyle as normative and hedonic goal framing have also been suggested as location choice motivators but were measured only indirectly through physical indicators. Further exploration of this topic is merited to better understand the residential choice of young people, people with high residential mobility and economic resources, and home renters. This line of research will also help understanding self-selection processes and counterintuitive residential choices such as in the case of long commuters.

Shared economy and rent-own models: Shared economy brings about new ways of community living and ownership patterns. One example is the Scandinavian rent-own model of shared apartments and houses, in which a few individuals or families from different households decide to share a dwelling unit, which is common space. The tenants are chosen based on group agreement and the apartments are designed from multiple households. The American example is the concept of companies offering fully furnished apartments in a community environment for short-term rental, which replaces the traditional rent agreements. Both models include private and commonly shared spaces, which redefine housing needs. They also redefine sharing as an amenity rather than a burden. From the residential location choice modeling, these new models are important because they allow affordable accessibility to the city center, where they are commonly located. Thus, understanding the trade-off between central shared dwelling units to suburban private dwelling units.

Soft location amenities: While much is known about the impact of physical location amenities and public services, very little is known regarding the impact of "soft" amenities including cultural and creative amenities, street art and vibrant street scene, digital amenities, sense of community and belonging, and coolness and networking factors. The literature on regional innovation and growth has long established valid indicators for "soft" amenities and linked "soft" amenities to economic growth, urban development, and regional attraction. The next step is to embed these amenities into residential choice models.

Introduction

The adoption of automobiles in modern society has caused traffic congestion in cities across the world, leading to problems such as long commutes, high-energy consumption, sedentary lifestyle, air pollution, and climate change. As the urban population continues to increase, accommodating the mobility of people and goods within the limited space of cities having highly competitive land uses has become a huge challenge for local governments.

Traditionally, countries such as the United States had tried to tackle the problem by increasing the “supply” of road capacity, by building more highways, bridges and tunnels to alleviate traffic congestion. While some developing countries, such as China, had been following this model, the approach had been largely criticized during recent years because the increased capacity actually induced more demand (Lee et al., 1999), resulting in same or more severe congestion. Under this background, the concept of “Transport Demand Management” (TDM, in many cases also referred as “Travel Demand Management”) was introduced since the 1970s in the United States (Meyer, 2016). As is suggested by its name, TDM promotes a new mindset to deal with the traffic congestion by focusing more on the better management of the “demand” side of transportation. The following sections provide an overview about the categories, measures, effects, and some selected case studies of TDM.

The State of the Art of Transport Demand Management

Ferguson (2000) identified three major categories of TDM solutions as “voluntarism”, “markets”, and “regulation” (Ferguson, 2000, pp. 57–270). His analysis has largely focused on the situation of US cities. Ison and Rye (2008) focused on the actual implementation and impact analysis of a range of TDM measures. They further refined the categories of TDM solutions into five, that is, “economic”, “land use”, “information for travelers”, “substitution of communications for travel,” and “administrative” (Ison and Rye, 2008, p. 1). The categorization is helpful but some categories like the “information for travelers” can be rather narrow. More recently, Meyer (2016) listed TDM goals, objectives, and performance measures from a more practical perspective of transport planning. Numerous other researchers have also looked into specific measures deemed successful in cities such as Singapore and London (Banister, 2008; May, 2004; Seik, 2000).

Table 1 General categories and effects of TDM measures

Categories	Measures	How many trips are made?	When are the trips made?	Where are the trips made?	How are the trips made?
		Reduce the number of trips	Shift trips from to nonpeak hours	Reduce trip distance and avoid congestion hotspot	Encouraging sustainable modes of transportation
Economic	Taxation	✓			✓

Most of the common measures of TDM are implemented in the form of public policy deeply rooted in the local cultural and political context of different countries. Therefore, the satisfactory implementation of one TDM measure in one country does not necessarily guarantee its success in another country. With this regard, it is more important to understand the nature of people's travel demand, as most human beings have the need to move themselves and their goods across space for the purpose of daily life. Specifically, four fundamental questions are asked to structure the analysis of TDM in this article: How many trips made? When are trips made? Where are trips made? How are trips made? These guiding questions are listed in [Table 1](#). Correspondingly, the four main goals of TDM measures are ways of reducing the number of trips, shifting trips from peak hours to other time, reducing average trip distance and avoiding congestion hotspot, as well as encouraging more sustainable modes/means of transportation. Specific policies from both developed and developing countries will be included in each section to provide an international perspective. In order to further enrich the analysis, we suggest a more general categorization of TDM measures, list out some common measures under each category, and highlight their relationships in answering the four key questions.

Addressing “How Many Trips are Made?”

When there is a high degree of concentration of people and goods, as is the case in most large cities today, it would be helpful to alleviate congestion by reducing the absolute number of trips made in the society. This can be achieved by more integrated land use and transport planning, and by promoting new work styles, such as e-working.

Promoting Mixed-Use Development

Compared to other short-term TDM measures, the management of land use is considered to be more of a long-term solution of easing congestions ([Meyer, 2016](#)). Generally, high-density, mixed-used urban environment would allow the citizens to fulfill their daily needs with the minimum number of trips per day with trip chaining at the same or nearby locations. For instance, it is typical for Hong Kong citizens to find restaurant and grocery stores at the ground floor of their apartment, meaning he/she will be able to fulfill the need of dining or buying groceries at his/her place of residence without making additional trips, while it is usual for those who live in detached single-family housing neighborhood in the United States to make a single-purposed trip to achieve the same purposes.

Telecommunications and E-Working

Telecommunications have been providing alternatives for traveling since the invention of fax machines (Ferguson, 2000). With the fast development of Internet and smartphones, many necessary trips in the past could now be simply replaced by a couple of clicks on smartphone applications. For example, one could easily use mobile banking service offered by most of the banks today to manage his/her accounts, and does not necessarily need to go the local bank branch for the same purpose.

It is also typical for companies today to hold teleconferences, which reduce the need for employees to travel to the same place. Meyer (2016) described a telework program operated by US Patent and Trademark Offices to allow the agency's employees to e-work almost every week. Other similar programs in the United States have reported both reduction of drive-alone trips and increase of employee's productivity (Meyer, 2016).

Although face-to-face interactions are still important (Hall, 2003), the fast advancement of technology provides some degree of substitution for travel. With the new generations of 5G and virtual reality technologies, it is reasonable to believe the experience of e-working would be further improved, which will attract more people to work at home, especially for those who need to make super-long commute in metropolitan areas. Therefore, there is a huge potential for telecommunications and e-working to help reduce the number of trips and ease traffic congestion.

Addressing "When are Trips Made?"

The capacity of transport infrastructure usually faces the greatest challenge during the peak hours. Therefore shifting some trips from peak hours to other regular hours would help alleviate the peak-hour congestion. Traffic information, as well as flexible work schedule, can help to achieve this goal.

Traffic Information

Information and communication technologies (ICT), or more specifically, services such as Google Map is now able to provide historic and real-time traffic information for travelers, allowing them to make smart decisions about the departure time of their trip to avoid time periods when congestion happens, and consequently spend less time traveling (Cohen-Blankshtain and Rotem-Mindali, 2016). As some informed users would shift their trips to noncongested periods, it is reasonable to argue that the peak-hour pressure on transportation infrastructure capacity will be alleviated by services of this sort.

Flexible Work Schedule

Since most of the commuting happens during peak hours, flexible work schedule can help reduce peak-hour traffic volume. In the United States, flexible work hours have been one of the major TDM programs (Meyer, 2016). A typical flexible work hours program can contain "core periods" and "flex periods" (Ferguson, 2000, p. 88), meaning that employees must be present at the office during designated core work hours, but could be absent during other time during the day. Staggered work hours is similar to flexible work hours in that employees may arrive or leave the work place at different time of the day, but this approach is rather unique in that it is the employer who decides and arranges the exact work shifts time, instead of the employee (Ferguson, 2000). Another popular approach is compressed weeks, meaning that employees could work more hours per day and work less number of days per week (Ferguson, 2000; Meyer, 2016).

As ICT continues to improve human connections without being together physically, flexible work schedule can become more popular as people may very well work with smart devices even when they are traveling (Wang and Loo, 2017). For instance, one may just write or reply to email on a bus to home, although he/she leaves office earlier than other coworkers.

Addressing "Where are Trips Made?"

Where people make their trips matters because recurrent congestion is the most common at some areas of the city. In addition, whether people have accessibility to employment and other services in nearby neighborhood will affect their trip distance. Congestion pricing can be used to reduce the volume of traffic in congestion-prone areas. Similarly, a better job-housing balance at the city level can also help reduce travel distance. In addition, distance-based charging can be applied to further discourage long trips.

Congestion Charging

Cordon-based congestion charging (also named congestion pricing) means that vehicles entering a designated area are charged. This policy is commonly applied to reduce the volume of traffic in the urban center, which is usually a congestion hotspot. An example of congestion pricing is the electronic road pricing (ERP) system in Singapore. If a vehicle enters the "Restricted Zone" (Seik, 2000, p. 36) during certain time periods, fees will be automatically charged with the help of the communication between the in-vehicle unit and the ERP system at the entry points of the restricted area (Seik, 2000). After the implementation of this system, the traffic flow fell by 20% to 24% during weekdays in the designated area, which covers the CBD of the city (Seik, 2000).

It is important to note that the ERP system were made possible by ICTs such as "radio-frequency, optical-detection, imaging, and smart-card technologies" (Seik, 2000, p. 36), which allows much more flexibility such as changing rates of charging throughout the day, when compared to the previous area license scheme in Singapore (May, 2004).

Similar policies have also been implemented in European countries. According to [Banister \(2008\)](#), London is the first city in Europe to practice congestion charging. First implemented in 2003, the measure reduced traffic level by 20% in the charging area ([Banister, 2008](#)).

Better Job-Housing Balance

Many modern cities have their employment centers located in the centers of the urban area, with most of the residence located in the peripheral area. As the metropolitan areas continue to grow, more and more people are involved in “super commute”. Therefore it is important to plan for job-housing balance to provide better accessibility to employment opportunities, especially for the peripheral area, and to reduce commuting time and distance.

Job-housing balance, however, is not listed in most existing literature as a measure of TDM, partly because it is more related to the field of land use planning. However, it is important to point out that, similar to transit-oriented development (TOD), coordinated land use planning can have great impact on transport demand and travel behavior, especially for developing countries where rapid urbanization is happening.

Distance-Based Charging

According to the [Ministry of Transport \(2019\)](#) in Singapore, the city is planning to integrate the distance-based charging mechanism into its current ERP system in 2020. This means drivers will be charged based on the distance they drive on congested road sections, whereas the original system charge the driver the same amount of fees regardless of their travel distance in the congested area ([Ministry of Transport, 2019](#)). It is reasonable to expect that this approach will further discourage long-distance travel in congested area, especially during peak hours. Again, this vision will be supported with the advanced ICT such as the global navigation satellite system ([Ministry of Transport, 2019](#)).

Addressing “How are Trips Made?”

In recent years, much effort has been spent on transport planning in different countries to promote the use of alternative modes of transport, instead of the use of private cars. As land resources become scarcer in big cities, the government needs to promote transport modes that have higher “space efficiency” ([Litman, 2014](#)). For the same number of people to move around, it is obvious that private cars take up much more road space, as well parking space, when compared to other modes of transportation, such as transit, cycling, and walking. Common measures to encourage the sustainable modes of transports are listed as follows.

Taxation

[Potter \(2008, p. 14\)](#) specified three types of taxation related to the use of automobiles, which are “tax on the initial purchase of a vehicle”, “ownership of vehicles”, and “the use of vehicles”. Taxation increases the cost of using private cars, and consequently promotes a modal shift from car to other modes of transportation. According to [Potter \(2008\)](#), this measure is widely applied in most of European Union countries, but are used more for the promotion of cleaner car technologies and less for the management of travel demand.

Vehicle Quota System

Compared to western countries, a rather strict policy called vehicle quota system has been implemented in Singapore, which directly limits the increase of the vehicle ownership by setting a predetermined “ceiling” each year ([Seik, 2000](#)). Similar policies have also been implemented in major cities in China, such as Shanghai, and have been proven to be effective ([Xiao et al., 2017](#)).

Parking Controls and Pricing

The use of private cars always leads to the problem of finding a parking space in crowded cities. [Shoup \(2005\)](#) pointed out the negative impacts of providing free roadside parking, as was the typical case in major cities in the United States. Furthermore, [Shoup \(2008\)](#) promoted an approach to charging the fee for parking space, which varies by time and location to resolve the problem of parking space shortage. Using this method, some of the original drivers will be discouraged to drive and will use other modes of transport instead, especially when provided with other incentives such as free transit pass ([Shoup, 2008](#)).

Encouraging Ride-Sharing (Carpooling)

Furthermore, in places where automobile-oriented infrastructure is already in place, TDM measures may be taken to promote carpooling to reduce the number of trips. A typical approach is to give priority to high occupancy vehicles, such as dedicating one lane on the highway for cars that has at least two passengers. In addition, there are also public agencies and private firms that provide “ride-matching services” ([Meyer, 2016, p. 648](#)).

Currently, a popular option for ride-sharing is through a common platform like UberPool, provided by the transport network company (TNC) known as Uber, which offers a lower price if the passenger is willing to carpool with other people going in a similar direction ([Uber, 2019](#)). As both the public and private sectors are now envisioning a future with autonomous vehicles, ride-sharing would be very important in reducing single-occupancy vehicle trips in future cities. It is possible that TNCs may play a key role in the promotion of ride-sharing if autonomous vehicles are to be operated by those types of companies in the future.

Public Transport Subsidization

Although some scholars have challenged the justifications of public transport subsidies, public transport is now heavily subsidized both in developed countries such as the United States (Van Reeve, 2008) and in developing countries such as China. Lowering the fares or public transport by subsidies helps encourage people to use transit instead of automobiles for their daily travel. This approach also helps to promote social equality by providing affordable transport options for socially disadvantaged groups (Preston, 2008). It is reasonable to argue that a strong local economy is required to provide sustainable funding to keep the subsidized public transport system running once it is built.

Transit-Oriented Development

TOD means putting intensive commercial and mixed-used development near or on top of transit stations or corridors. People living in such kind of environment may easily fulfill their daily needs around transit stations, therefore are more willing to use transit as their means of transport.

This type of transport-land use coordination can be promoted through regional planning organizations, such as the Metropolitan planning organization (MPO) in the United States. For example, the Southern California Association of Governments is the largest MPO in the United States, which is responsible for making regional transport and land use policies for six counties in California (Southern California Association of Governments, 2019). Through making the regional transportation plan/sustainable communities strategy, the agency aims to channel the new land use development to the transit station or transit corridors (Southern California Association of Governments, 2019).

Urban Design and Site Design

Loo and du Verle (2017, pp. 55–66) pointed out that future TOD strategies should not only focus on the patronage of transit system itself, but also consider the design features such as “greenery” and “vibrancy” near transit stations. Urban design and site design features can influence people’s travel behavior in a very subtle but significant way. Based on the above understanding, government has started to make design guidelines that encourage the use of the alternative modes of transportation.

In Europe, countries such as the United Kingdom and Sweden have developed planning and design guidelines that require the promotion of sustainable modes of transport during the project planning and approval process (Black and Shreffler, 2010). In London, specific methods are described in the Streetscape Guidance—a set of street design guidelines to create high-quality street environment and to make walking, cycling, and transit use more attractive (Transport for London, 2019).

In New York, a policy document named Active Design Guidelines is used to encourage active transport (Meyer, 2016). While the design guidelines focus more on improving public health, the promotion of walking and cycling will also help to manage traffic demand and reduce the dependency on automobiles (Center for Active Design, 2010).

Park and Ride Facilities

Park and ride facilities give the drivers opportunities to park their vehicles and switch to public transport, usually at the edge of urban areas (Meek, 2008). This measure is mainly used for promoting the use of public transport and has been widely applied in countries such as the United States and the United Kingdom (Lam et al., 2001). As large transport hub continues to emerge in big cities, this concept may further evolve at the age of autonomous driving, such as giving people opportunities to switch from autonomous automobiles to transit when traveling into urban center.

Mobility as a Service

In recent years, there are increasing discussions about the mobility as a service (MaaS), which aims to provide mobility options as services that could be subscribed through integrated online platforms. The concept was first introduced by Sampo Hietanen, who defined MaaS as “a mobility distribution model in which a customer’s major transportation needs are met over one interface and are offered by a service provider” (Hietanen, 2014, p. 2). Under this concept, people’s daily travel demand would be fulfilled by an integrated package of transportation services, which guarantee the level of the reliability and convenience comparable to having a car, which as a result will reduce citizen’s car ownership. It is important to acknowledge that this new concept is largely enabled by the advancement of ICT technologies. Jittrapirom et al. (2017) summarized nine core characteristics of MaaS, almost all of which are enabled by current data integration technology, location-based services, as well as web and mobile interfaces technologies (Hietanen, 2014). This paradigm has gained popularity since it promises to bring benefits to different parties, including transport users, private service providers, and public sectors, by taking full advantage of the ICT technology to better match supply and demand (Hietanen, 2014). Although limited research had been done to investigate the real impact of the pilot MaaS programs around the world (KiM Netherlands Institute for Transport Policy Analysis, 2018), it is reasonable to expect the potential of well-designed MaaS programs to tackle automobile-dependency and alleviate congestion.

School and Tourist Transport Management Programs

As many trips are generated by students traveling between home and school, specific programs are also developed to better manage this type of travel activities. In the United States, various measures have been implemented at different school levels to reduce automobile dependency, such as providing free access to transit, mobility education programs, etc. (Washington State Transportation Commission, 2009).

Tourist transport management programs can also be used to alleviate traffic congestion while accommodating the mobility needs of tourist. For example, based on the prediction from travel forecasting model, the Salt Lake City Olympic Committee provided a transportation guidebook for people visiting the city for the Winter Olympic Game, which specified tips on how they could navigate through the city efficiently (Transportation Research Board, 2004).

Conclusion and Discussion

By answering the four fundamental questions, common TDM measures being implemented in cities across of the world were discussed. As the problem of congestion becomes more severe in metropolitan area, learning from the successful experience of managing transport demand will be helpful. These measures, though described separately, should be better integrated into holistic policy packages (Meyer, 2016) and fundamental city transformations at different spatial levels (Loo and Tsoi, 2018).

Although technological TDM measures may be listed as a separate category, they actually support and underlie different TDM measures. For instance, congestion pricing, distance-based charging, and ride-sharing would not be successful without the support of the state-of-art ICT. As Gillen (2008) has pointed out, ICT has helped to provide information, direct traffic, automate tasks, and monitor the performance of the road-pricing efforts. Looking ahead, the next generation of ICT (such as the 5G technology), combined with robotics, automation, and artificial intelligence technology, are likely to bring new tools, as well as new challenges, to the field of TDM.

With all the technological advancement mentioned above, the world is expected to enter an age of ubiquitous connectivity, potentially resulting in a dramatic change of people's lifestyle. Some traditional trips can be further replaced by e-working or other online activities. Some trips can be further directed to nonpeak hours as work schedules could become increasingly flexible. On the other hand, activities that need frequent face-to-face interaction are still likely to concentrate in urban centers (Hall, 2003), and cities would still be challenged with the problem of space scarcity in the foreseeable future. Therefore encouraging people to switch to transport modes with higher space efficiency (i.e., transit, cycling, walking) is necessary. All these may be achieved by thoughtful urban planning and economic measures, as well as innovative MaaS programs.

Last but not least, as the transport industry is increasingly focusing on the implementation of autonomous driving, some scholars and practitioners (Calthorpe and Walters, 2017; Litman, 2019) have warned about the dystopia scenario of implementing autonomous driving technology, where convenient autonomous vehicle services can induce people to travel more and travel longer distance, and consequently leading to urban sprawl and congestion problem at a larger scale than what we witness today. Therefore regulations by the public sector would be essential to harness the benefits of these types of technology and to avoid the potential negative impacts. With this regard, careful research and policy design for TDM will continue to be an important field in the years to come.

Basic Tools and Definitions

In this section, we introduce two basic tools to describe traffic flow at the individual vehicle level, namely the time-distance trajectory of a vehicle and the cumulative "curve" of vehicle counts at a specific location over time or at a specific time over space. We will use these geometric constructs to show how variables of interest, such as time headway, spacing, flow rate, speed, and density are defined and measured.

Vehicle Trajectory

Imagine that one can install a Global Positioning System (GPS) device on each vehicle, and from which one can deduce at each time instant, the distance traveled by that vehicle. Let $x_n(t)$ denotes the distance traveled by vehicle n , then the plot of $x_n(t)$ against time t is called the vehicle trajectory of n . With this trajectory, one knows the speed and acceleration of each vehicle:

$$\text{Speed : } v_n(t) = \frac{dx_n(t)}{dt}, \quad \text{Acceleration : } a_n(t) = \frac{dv_n(t)}{dt} = \frac{d^2x_n(t)}{dt^2}$$

One can also compute the vehicle-miles-traveled (VMT) of this vehicle from $t = t_1$ to $t = t_2$: $\text{VMT} = x_n(t_2) - x_n(t_1)$, or vehicle-hours-traveled from x_1 to x_2 : $\text{VHT} = x_n^{-1}(x_2) - x_n^{-1}(x_1)$, where $x_n^{-1}(x)$ is the inverse function of $x_n(t)$ (see Fig. 1).

If we collect the trajectories for a group of vehicles, as shown in Fig. 1, we have a complete description of the traffic dynamics of this group of vehicles. Note that $x_n(t)$ is the distance traveled by a vehicle, these trajectories cannot bend backward. In one-lane traffic without passing, these trajectories will not cross each other, but in multilane traffic, vehicle trajectories do cross each other and can pop up or disappear due to passing, lane changes, entries and exits.

Cumulative Curves

A cumulative curve of traffic arrivals to a fixed location of the highway (x) is constructed by recording the arrival time of each vehicle at that location and increment a counter by one for each arrival. This "curve" is actually a staircase function with the vertical axis being the total vehicle counts N and the horizontal axis being observation time t , as shown in Fig. 2 for locations x_1, x_2 . But as arrivals become more frequent (i.e., the flow is high), the steps become narrower and one can approximate this staircase by a smooth curve $N(x, t)$, hence the name cumulative curve. Similarly, a cumulative curve of traffic passing any location of the road at a time instant t can be constructed by recording the location of each vehicle at that time, and counting the number of vehicles that has passed that location, as shown in Fig. 3 for two time instants t_1, t_2 .

Figure 1 Vehicle trajectory diagram.

Figure 2 Cumulative vehicle counts passing fixed locations, observed over time.

Figure 3 Cumulative vehicle counts passing any location, observed over space.

From the cumulative curve 28.2, one can know the average intensity of arriving flow in time period $t = [t_1, t_2]$: $q(x; t_1, t_2) = \frac{N(x, t_2) - N(x, t_1)}{t_2 - t_1} = \frac{\Delta N}{\Delta t}$. When $t_2 \rightarrow t_1 = t$ and $N(x, t)$ is smooth, we have the point intensity, or flow rate, as $q(x, t) = \frac{\partial N(x, t)}{\partial t}$. Another important variable that can be obtained from the arrival cumulative curve is the inter arrival times between successive vehicles, known as time headway or simply headway: $h_n = t_n - t_{n-1}$, where t_n is the arrival time of vehicle n at the observed location. For a sufficiently large Δt , we have $\sum_{n=1}^N h_n = t$, or $q = \frac{N}{\sum_{n=1}^N h_n} = \frac{1}{h}$.

Form the cumulative curve 28.3, one can get the concentration or density of vehicles on the road in a given road segment $x = [x_1, x_2]$: $k(x_1, x_2; t) = \frac{N(x_2, t) - N(x_1, t)}{x_2 - x_1} = \frac{\Delta N(x, t)}{\Delta x}$. Again, when $N(x, t)$ is treated as a smooth curve, one has $k(x, t) = -\frac{\partial N}{\partial x}$, with the negative sign reflecting the fact the total number of vehicles passing a downstream point (here x_2) is no more than the total number of vehicles passing an upstream point (here x_1). From Fig. 3, one can also obtain the space headway between successive vehicles on the road, or spacing (usually measured from head to head or tail to tail): $s_n = x_{n-1} - x_n$. For a sufficiently large Δx , we have $\sum_{n=1}^N s_n = x$, or $k = \frac{N}{\sum_{n=1}^N s_n} = \frac{1}{s}$.

Vehicle counts and headway are of fundamental interest to many transportation problems, such as traffic safety and traffic signal timing. While in heavy traffic situations it is common to treat the arrivals to a location as deterministic and use cumulative curve $N(t)$ (here x is suppressed) to model the arrival process. In light traffic situations the stochastic nature of the arrival process dominates and $N(t)$ is often treated as a random variable. A common probability distribution used for traffic counts for a given time interval $[0, t]$ is

Figure 4 The definition of flow variables on a trajectory map.

the Poisson distribution with mean arrival rate q :

$$P(N(t) = n) = \frac{(t)^n e^{-qt}}{n!} \quad (1)$$

whose headway h has a negative exponential distribution:

$$P(h < t) = 1 - e^{-qt} \quad (2)$$

The Poisson distribution can also be applied to vehicle counts in a road section $[0, x]$ in light traffic situations with q replaced by k and t by x . The Poisson model is extensively used in traffic delay analysis for light traffic situations.

Traffic Flow Measurements and Variable Definitions

As we have illustrated in the vehicle trajectory concept, the ultimate way of measuring traffic is to track each vehicle continuously with GPS or other devices. For economic, privacy and other considerations, this is often not feasible. In contrast to such mobile sensing, the most common ways of measuring traffic flow are through installation of nonmobile sensors at fixed locations, such as inductive loops, video or microwave sensors. It is not the interest of this chapter to cover the specific sensing technologies. It is suffice to say that these nonmobile sensors map out a "measurement area" dA in the time-distance trajectory diagram, as shown in **Fig. 4**, and for each vehicle n inside this area, its travel time dt_n and travel distance dx_n . We then can define the average traffic flow rate, density, and speed as follows:

$$\text{Flow rate : } q = \frac{\sum_n dx_n}{dA} \quad (3)$$

$$\text{Density : } k = \frac{\sum_n dt_n}{dA} \quad (4)$$

$$\text{Speed : } u = \frac{\sum_n dx_n}{\sum_n dt_n} \quad (5)$$

By definition, we have $q = ku$. The average speed thus defined is also known as the space-mean speed. For a sensor that measures traffic within a fixed length dx , all vehicles measured within a given time interval T travels the same distance $dx_n = dx$ (we assume that dx is small enough that vehicles do not leave in the middle of it). Then Eq. (5) gives the following formula:

$$\text{Speed : } u = \frac{\sum_n dx}{\sum_n dt_n} = \frac{N}{\sum_{n=1}^N \frac{1}{v_n}} \quad (6)$$

which is known as the harmonic mean of individual speed $v_n(dx_n/dt)$. The arithmetic mean

$$v = \frac{\sum_n dx/dt_n}{N} = \frac{1}{N} \sum_{n=1}^N v_n \quad (7)$$

is known as the time-mean speed when individual speeds are measured at a fixed location over time. Time mean speed is always larger or equal to space speed and usually $q \neq kv$. Although time-mean speed is often used in spot speed studies, it is much less relevant in traffic flow analysis. Unless stated otherwise, the mean speed we use throughout this chapter is the space mean speed according to definition (5).

Figure 5 The flow-density plot from measured data on the fast lane of I-180 near Davis, California.

Another important measurement of interest is *travel time* or *travel delay*. For an individual vehicle n , its trajectory provides a direct way of getting its travel time between any two locations x_1 and x_2 ($x_2 > x_1$): $t_n(x_1, x_2) = x_n^{-1}(x_2) - x_n^{-1}(x_1)$ where $x_n^{-1}(x)$ is the inverse function of the trajectory $x_n(t)$. From $t_n(x_1, x_2)$, one can compute the population or sample mean of travel times, depending whether all the vehicles in the traffic stream or a sample of vehicles in the traffic stream have been measured with a vehicle positioning sensor.

The concept of delay depends on the definition of a reference travel time t_r , for example, the time it takes to traverse the $[x_1, x_2]$ section with the maximum travel speed (say the speed limit). Once this reference time is decided, the delay of vehicle n can be computed as

$$\text{Delay : } d_n(x_1, x_2) = t_n(x_1, x_2) - t_r \quad (8)$$

When traffic is not measured by mobile sensors, one can use the cumulative arrival curve to obtain the vehicle travel times, as shown in Fig. 2, which requires the construction of cumulative arrival curve $N(x_1, t)$ at location x_1 and $N(x_2, t)$ at location x_2 . The horizontal separation between these two arrival curve at $N(x_1, t_1) = N(x_2, t_2) = n$, is vehicle n 's travel time. The delay of vehicle n is its travel time subtract t_r , which is equivalent to shift the $N(x_1, t)$ curve to the right by t_r . It must be pointed out that this way of obtaining travel times or delays over a road segment depends on the assumption that vehicles do not pass each other (or vehicles obey first-in-first-out [FIFO] rule in queuing jargon). It can still be used to estimate travel times or delays when FIFO is obeyed by most vehicles.

Last but not least, the *vehicle-miles-traveled* (VMT) and *vehicle-hours-traveled* (VHT) in measurement area dA are simply $\text{VMT}(dA) = \sum_n dx_n$ and $\text{VHT}(dA) = \sum_n dt_n$, and that for the total road system would be $\sum_{dA} \text{VMT}(dA)$ and $\sum_{dA} \text{VHT}(dA)$ when all road segments of the system are measured in a given time period.

Stationary Traffic Flow Models

From empirical data, the flow rate, density and speed measured at highway locations have shown to exhibit certain relations when plotted against each other, as shown in Fig. 5. Such plots often contain stationary and transient traffic conditions. Here we define stationarity as the condition that flow rate, density and speed remain nearly constant for a period of time (usually longer than a minute). Studies have shown that the flow rate, density, and speed at a location under stationary conditions observe well defined relations (Castillo et al., 1995; Cassidy, 1998). These pair-wise relations are known as traffic stream models, with the flow-density relation in particular being referred to as the fundamental diagram of traffic flow, although from a driver's perspective, the speed-spacing or speed-headway relation is more natural and fundamental to understand her driving behavior.

There have been various models proposed for the fundamental diagram of traffic flow, with the earliest being the model proposed by Greenshields et al. (1935)

$$q = v_f(k - k^2/k_j) \quad (9)$$

where v_f is the free-flow speed (or speed limit since it is obtained at $k = 0$), and k_j is the jam density (when traffic is not moving or $u = 0$). The corresponding speed-density relation of Greenshield's model is given as $u = v_f(1 - k/k_j)$, a linear function of density.

Figure 6 The triangular fundamental diagram.

Typical of the fundamental diagram (FD), the Greenshields FD has a maximum flow q_* at a particular density k_* . q_* is known as the capacity of the road at that location and k_* is known as the critical density. In the case of Greenshields FD, $k_* = k_j/2$ and $q_* = (u_f k_j)/4$. For a road with a free flow speed of 95 km/h and jam density of 143 car per km (5 m car length plus 2 m buffer between stopped cars), the maximum flow $q_* = 3396$ cars per hour greatly exceeds what one observes from real-life traffic. In the literature, unrealistically low jam densities are used to make the Greenshields FD produce realistic flow capacities.

There is another important quantity associated with the FD, which is the derivative of the flow with respect to density at $k = k_j$: $w_j = \frac{dq}{dk}|_{k=k_j}$. This quantity is known as the wave speed at jam density, which captures how quickly the front of a discharging queue with jam density moves upstream, and is known to be around -20 km/hr in most situations (see Chapter 5 of [Gartner et al., 2001](#)). Again for the Greenshields FD, this speed $w_j = -u_f$, which is in the range of -88 km/h to -120 km/h for most freeways, and clearly inconsistent with field observations.

While the Greenshields' FD played a pioneering role in the development of traffic flow theory, its drawbacks have long been recognized. Subsequent research on traffic stream characteristics produced a large number of traffic stream models, ranging from smooth Greenshields like models, models with a jump at or near the critical density, to even multi-valued functions with hysteresis (see [Gartner et al., 2001](#), Chapter 2 for a comprehensive review). The more exotic models, however, were developed to fit traffic data that contain both stationary and transient states, and are often under the influence of active bottlenecks. They do not reflect the traffic stream characteristics under stationary conditions.

Regardless which FD one chooses, one should check if the FD has reasonable free-flow speed and jam density, and produces reasonable flow capacity, critical density, and jam wave speed, all measurable quantities from field that can be used to validate the FD model. It turns out that there is a simple FD that meets all these requirements. It is the so-called triangular FD, given by the following equations:

$$q = \begin{cases} ku_f & k \leq k_* \\ |w_j|(k_j - k) & k \geq k_* \end{cases} \quad (10)$$

This FD has four parameters, u_f, k_j, w_j, k_* , all can be directly measured (the first three) or estimated from measurements (k_*). Only three of them are needed to determine the FD. The flow capacity is controlled by u_f, k_j , and w_j . As in the Greenshields' example, a road location with $u_f = 95$ km/h and $k_j = 143$ cars per km would have the capacity $q^* = 2363$ cars per hour for $w_j = -20$ km/h, which is in accordance with observed capacities for such roads.

Fig. 6 shows the triangular FD. As we shall show in the next section, this FD is particularly attractive when one studies traffic congestion using the piped traffic flow models, particularly the kinematic wave model known as the Lighthill-Whitham-Richards (LWR) model ([Lighthill and Whitham, 1955](#); [Richards, 1956](#)). Nevertheless, this FD is not without its own drawbacks. For example, the free-flow branch has only one speed, which is not fully consistent with observed traffic stream characteristics. The same is true for the congested branch. These can be overcome by using piece-wise linear FDs, as shown in **Fig. 7**, if field observations call for the use of such FDs.

The FDs capture the bulk of our driving behavior and is an essential element of traffic flow analysis. They or their variants are extensively used in dynamic traffic flow modeling (see the next section), transportation planning, and highway capacity and level of service analysis ([TRB, 2016](#)).

Dynamic Traffic Flow Models

This section presents three families of dynamic traffic models that describe traffic in different levels of detail. Using a fluid flow analogy, we call them (1) *particle tracing models* where each individual vehicle's movements are modeled, this family of models contain the so-called car-following models and cellular automaton models, and are known as microscopic models; (2) *piped traffic flow models* where highway traffic is treated like a fluid flowing in a pipe, this family of models are known by various names in the

Figure 7 An example of a piece-wise linear fundamental diagram.

literature, including hydro dynamic models, kinematic wave models, and higher-order models, to name a few; and (3) *reservoir traffic flow models* where an entire city or blocks of a city are treated as a reservoir with entering and exiting flows through both the boundary and internally, some of these models known by names such as two-fluid town models or town models with a macrofundamental diagram (MFD).

Particle Tracing Traffic Models

Car-Following Models

A car-following model describes the movement of a vehicle constrained by its interactions with nearby vehicles. Although a driver pays attention to all surrounding vehicles, her predominant focus is often on the vehicle ahead of her. Most car-following models, therefore, were developed for a pair of vehicles, the following vehicle n and the front vehicle $n - 1$. Let $x_n(t), x_{n-1}(t)$ denote the positions (by its traveling distance from a reference point) of vehicle n and $n - 1$ respectively, and $v_n(t), v_{n-1}(t)$ their respective velocity, and $a_n(t), a_{n-1}(t)$ their respective accelerations. A car-following model predicts the movement of vehicle n described by the triplet $\{x_n(t), v_n(t), a_n(t)\}$, depending on the movement of the preceding vehicle $(n - 1) - \{x_{n-1}(t), v_{n-1}(t), a_{n-1}(t)\}$ from $t = 0$ to some terminal time $t = t_e$.

The simplest car-following model is perhaps the one derived from a common recommendation to drivers, which are known as the one-car length or 2-second rule:

One-car length rule: For every 10-mph speed of travel, leave one-car length space between your car and your front car.

2-second rule: Keep 2 s of time gap between you and your front car.¹

We can construct the trajectory of car n if we know the trajectory of car $(n - 1)$ for drivers who strictly follow these rules. In the case of the one-car-length rule, this is equivalent to

$$x_{n-1}(t) - x_n(t) - l_n = \left(\frac{v_n(t)}{10}\right) l_n \quad (11)$$

where l_n is the length of car n . And in the case of the 2-s rule, it is equivalent to

$$(x_{n-1}(t) - x_n(t) - l_n)/v_n(t) = 2 \quad (12)$$

In fact, if we define a new parameter $\tau = l_n/10$ in Eq. (11) and $\tau = 2$ in Eq. (12), both equations can be translated into the same equation:

$$v_n(t) = \frac{x_{n-1}(t) - x_n(t) - l_n}{\tau} = \frac{S_n(t) - l_n}{\tau} \quad (13)$$

$$a_n(t) = \frac{v_{n-1}(t) - v_n(t)}{\tau} \quad (14)$$

Eq. (14) tells us that according to these driving rules, the following driver should accelerate with a rate proportional to their velocity difference, that is, if the car in front travels faster than you, you accelerate; if it travels slower than you, you decelerate; and if it travels at the same speed as you, you cruise.

Since drivers have to respect the speed limit of the road, we impose a speed limit u_f to Eq. (13) to get

$$v_n(t) = \min \left\{ u_f, \frac{S_n(t) - l_n}{\tau} \right\} \quad (15)$$

¹ In practice, a driver is recommend to identify a target spot on the road and reach that spot two seconds after her front car. This is the time headway as we defined earlier.

Then the position of vehicle n can be obtained by integrating speed over time:

$$x_n(t) = \int_0^t v_n(t) dy \quad (16)$$

Using car-following models like this, one can obtain the vehicle trajectories of a stream of vehicles $n = 1, 2, \dots, n, \dots, N$ by solving a system of equations consisting Eqs. (15) and (16), as long as the initial position and velocity of each vehicle is known, and the trajectory of the leading vehicle is also known (in the case of a closed system such as vehicles traveling on a ring road, only the initial conditions need to be known). From the vehicle trajectories, one can compute the flow variables such as flow rate, density, speed, travel time/delay, and VMTs and VHTs as described in Section Basic Tools and Definitions.

Besides some simple car-following models like Eq. (15), one has to resort to numerical solutions to obtain approximate vehicle trajectories by discretizing the car-following equations in time. Under special situations, one does not need to solve these equations explicitly to gain insights of the behavior of such models. One such a special condition is when traffic is stationary. Without loss of generality, let's assume the cars are of the same length l . Further denote the stationary speed as u and spacing as s . Under stationary conditions, Eq. (15) becomes

$$u = \min \left\{ u_f, \frac{s-l}{\tau} \right\} \quad (17)$$

and taking into account that $s = 1/k$, and $l = 1/k_j$, the stationary flow rate is

$$q = ku = \min \left\{ ku_f, k \frac{1/k - 1/k_j}{\tau} \right\} = \min \left\{ ku_f, \frac{l}{\tau} (k_j - k) \right\} \quad (18)$$

Eq. (18) gives exactly the triangular FD, and is identical to Eq. (10) with $w_j = -l/\tau$. This also provides a way to estimate τ if w_j is known or w_j when τ is known. This connection between the triangular FD and the car-following model also provides the behavioral grounding for the triangular FD.

The study of car-following has a rich history in traffic flow analysis and what was discussed above shows a simple example of how such models can be developed based on the understanding of driving rules. In real life drivers could not perceive the relative speeds or distances precisely, and have different levels of cognitive and driving capabilities as well as different driving habits. These factors lead to more complex traffic dynamics and nonlinear car-following models to describe them. A fairly general nonlinear car-following model is given by the following equation (Gazis et al., 1961):

$$a_n(t+T) = b(v_n(t))^\alpha \frac{v_{n-1}(t) - v_n(t)}{(x_{n-1}(t) - x_n(t))^\beta} \quad (19)$$

where T is a time lag that reflects a driver's reaction time to respond to changes in relative spacing and speeds, and b, α, β are parameters to be determined through fitting car-following data. Interestingly, this model reduces to a linear model almost identical to (14) with $\alpha = 0, \beta = 0, b = 1/\tau$. There is a fundamental difference, however, between this reduced model and (14). Due to the introduction of a time delay (T), the reduced linear model can be unstable if the values of bT is large enough, while the model given by (14) is always stable. By instability we refer to the property that small changes introduced in the speed of the leading vehicle get magnified over time through a string of vehicles behind it. Time delay is not the only factor that can cause instability in car-following. Certain types of nonlinearity can also produce instability, such as in the [Bando's model](#). Another interesting special case of this model is when $\alpha = 0, \beta = 2$. This reduced model leads to the Greenshields FD under stationary traffic conditions.

Numerical Solution and Traffic Simulation

The car-following models described above are all in the form of ordinary differential equations (ODE), some are linear and others are nonlinear. Besides the linear and some special nonlinear car-following models that can be solved analytically, most of them has to be solved numerically. A common practice is to divide the time into intervals with equal increment, say Δ : $\{t_0, t_1, t_2, \dots, t_j, t_{j+1}, \dots\}$, $t_{j+1} - t_j = \Delta, \forall j$, and use difference equations to replace the original differential equations with a suitable approximation of the derivatives. One simple such scheme is the so-called Euler difference scheme, which uses $\frac{v(t_j) - v(t_{j-1})}{\Delta}$ to approximate $\frac{dv}{dt}$. Using this scheme, the difference equation for the general nonlinear model (19) is

$$\frac{v_n(t_{j+1} + T) - v_n(t_j + T)}{\Delta} = b(v_n(t_j))^\alpha \frac{v_{n-1}(t_j) - v_n(t_j)}{(x_{n-1}(t_j) - x_n(t_j))^\beta} \quad (20)$$

One can then update the position of each vehicle from time t_j to time t_{j+1} as follows:

$$x_n(t_{j+1}) = x_n(t_j) + v_n(t_{j+1}) \quad (21)$$

Suppose we know the initial conditions at time t_0 : $(x_n(t_0), v_n(t_0)), \forall n$ and the speed of the leading vehicle $v_1(t)$, then one can advance the position of each vehicle n from one time interval to the next, until the end of the specified time. Such difference solution schemes give rise to microscopic traffic simulation. In these simulations, only the time t is discretized into equal increments. There is

a family of models, known as particle hopping or cellular automaton models, that discretize both time and distance. The unit of discrete distance x is called a cell and its length is usually set to 7 m, a car length (with safety buffer when stopped). A car therefore occupies one cell and hops into another cell based on its current speed, which is measured in cells per time tick. Rules can then be specified on how cars hop among cells (Nagel and Schreckenberg, 1992). The advantages of this family of models are their simplicity, flexibility in specifying driving rules, and amenity to parallel computation.

Of course there is much more to a traffic simulation of a highway network than what is shown here. For example, one needs to specify lane change rules, paths taken by vehicles, and right-of-way rules at junctions, to name a few. Interested readers are referred to Gartner et al. (2001) for further reading.

A traffic simulation produces a piece-wise linear trajectory of each simulated vehicle. One can therefore use the methods in Section Basic Tools and Definitions to obtain performance measures such as travel time, travel delay, and VMTs for each vehicle or the entire simulated highway network from a microscopic traffic simulation.

Piped Traffic Flow Models

The LWR Model

Proposed by Lighthill and Whitham (1955) and Richards (1956), the LWR model borrows the idea from hydrodynamics: traffic propagation can be described as waves, which are called kinematic waves (KW).

Model formulation The LWR model is essentially a conservation equation (i.e., conservation of vehicles) coupled with the flow-density fundamental diagram obtained from stationary flow conditions:

$$k_t + Q(k, x)_x = 0 \quad (22)$$

where the subscripts t and x denote partial derivatives, and $Q(k, x)$ is a suitably chosen fundamental diagram that can vary by location (x). This is a partial differential equation derived from the integral equation of flow conservation

$$\frac{d}{dt} \int_x^{x+dx} k(x, t) dx = Q(k(x, t), x) - Q(k(x + dx, t), x + dx) \quad (23)$$

For the clarity of presentation, we show the properties of the LWR model with the simpler case where the FD is not dependent on location, that is, $Q(k, x) = Q(k)$ (the same approach can be applied to the inhomogeneous case with $Q(k, x)$ but it is more involved and is beyond the scope of this book). The solution uniquely exists for the LWR model when proper initial and boundary conditions are specified, and an additional condition called *entropy condition* is applied. The LWR model is a hyperbolic partial differential equation, whose properties are well studied. Characteristics $x_*(t)$ of the LWR model are defined as:

$$x_*(t) : \frac{dx}{dt} = Q'(k) \quad (24)$$

where $'$ denotes the derivative of a scalar function (e.g., $Q'(k) = dQ/dk$).

It can be verified that the characteristics defined above are straight lines, because along the $x_*(t)$, there is

$$\frac{dk}{dt} = k_x + k_t x'_*(t) = k_x + k_t Q'(k) = k_t + Q(k)_x = 0 \quad (25)$$

that is, k is constant on the characteristic $x_*(t)$. This property may be interpreted as characteristic lines carry the information about density. This requires $Q'(k)$ to be bounded for the LWR model to make physical sense, meaning information in traffic flow must propagate at finite speed.

Shock waves and rarefaction waves: If one examine the characteristic lines of the LWR model further, one may find in many cases, characteristic lines will cross each other. Therefore, to determine the solution, one must choose a proper value for density at this point. This basic observation motivates two most important concepts in the hyperbolic conservation equations (the mathematical theory behind the LWR model), namely weak solution and entropy condition. Rather than presenting the entire theory (see e.g., LeVeque, 1992), we illustrate properties of the LWR model through the so-called Riemann problem, which considers traffic evolution with piece-wise constant initial data (k_L, k_R) and a discontinuity at $x = 0$, as illustrated in Fig. 8.

The Riemann problem of LWR model leads to two types of waves, namely shock wave and rarefaction (expansion) wave. They arise under the following conditions:

- Shock wave: if and only if $k_L < k_R$
- Rarefaction wave: if and only if $k_L > k_R$

The first condition means upstream traffic is lighter than downstream traffic, therefore traveling faster. It models the situation when fast traffic catches slow traffic. In this case, a queue forms, and a shock wave describes how queue-ends move. A vehicle enters a shock will decrease its speed abruptly. The second condition describes the opposite case. In this case, the discontinuity in initial

Figure 8 Illustration of a Riemann problem.

Figure 9 Two basic waves associated with the LWR model.

Figure 10 Cell discretization of traffic flow problems.

density profile will disappear, and the two states will be connected by a rarefaction fan. A vehicle enters the fan will accelerate smoothly until it travels out of the fan. Fig. 9 illustrates the difference between these two waves and depicts how the wave speeds are determined.

The Riemann problem with these two waves form the basis of the LWR theory to solve more complicated conditions, when general initial data are given. However, to solve such general problems analytically are tedious, if not difficult. Numerical solution schemes are therefore developed, with special care to treat shock conditions.

Numerical scheme: The common approach to solve the LWR model is through discretization of space into cells and update traffic state in each cell over discrete time steps (see Fig. 10). Then the LWR model can be numerically solved by

$$k_{n,t_j+1} = k_{n,t_j} + \frac{t}{x} (q_{n-1/2,t_j} - q_{n+1/2,t_j}) \quad (26)$$

This translates the problem into determining the corresponding numerical fluxes $q_{n-1/2,t_j}$ and $q_{n+1/2,t_j}$ based on the solutions to the corresponding Riemann problems (the initial density, when given in a continuous form, is approximated by a piece-wise constant staircase function).

It turns out that the numerical flux to the LWR model can be analytically derived from the solution of the Riemann problem at the cell boundaries. In transportation literature, this is known as the supply-demand scheme (Daganzo, 1994; Lebacque, 1996), written as follows (subscripts of time are omitted here)

$$q_{n-1/2} = \min\{D_{n-1}(k_{n-1}), S_n(k_n)\} \quad (27)$$

Here, $D_{n-1}(\cdot)$ and $S_n(\cdot)$ are respectively demand and supply functions of cell density for cells $(n-1)$ and n . For any cell, these functions are defined as,

$$D(k) = Q(\min\{k, k_*\}), S(k) = Q(\max\{k, k_*\}) \quad (28)$$

where k_* is critical density of the fundamental diagram. These functions can be expressed more explicitly as

$$D(k) = \begin{cases} Q(k) & k \leq k_* \\ Q(k_*) & \text{otherwise} \end{cases} \quad (29)$$

$$\text{and } S(k) = \begin{cases} Q(k) & k \leq k_* \\ Q(k_*) & \text{otherwise} \end{cases} \quad (30)$$

It is noted that when $Q(k)$ takes the form of the triangular FD, the LWR model is greatly simplified and can be solved easily without resorting to numerical solutions. The solution space is comprised of polygons, with each polygon defining an area of constant density/speed/flow. The boundaries of the polygons are the shock or rarefaction waves determined by the density on both sides of the edge of a polygon. The construction of these polygons are made particularly easy if one takes a variational approach by using the cumulative count $N(x,t)$ instead of density $k(x,t)$ in the LWR model (Daganzo, 2005; Newell, 1993).

Nonequilibrium Models

At the core of the LWR model is the FD, $Q(k)$, which captures the behavior of traffic under stationary conditions. Real traffic flow contains transient conditions and the FD is inadequate to represent such conditions. Nonequilibrium traffic flow models such as the one developed by Payne (1971) and Whitham (1974), adds a so-called equation of motion to the conservation equation $k_t + (ku)_x = 0$:

$$\frac{du}{dt} = u_t + uu_x = \frac{u_*(k) - u}{\tau} - \frac{c^2(k)}{k} k_x \quad (31)$$

The first term on the right hand represents relaxation of speed to the equilibrium state $u_*(k)$, and the second term represents a driver's response to gradient of density, which is known as the anticipation term.

Unlike the LWR model, the PW model comprises a system of PDEs with variables k, u (or k, q). The properties of nonequilibrium models can be subtle, which triggered extensive discussions on this topic. Among others, one puzzle was that there is a family of waves in the PW model that can travel faster than traffic (Castillo et al., 1993; Daganzo, 1995b), which leads to the situation that vehicles can "push" or "pull" vehicles from behind to speed up or slow down (Zhang, 1998, 2000). This puzzle was later resolved in Aw and Rascle (2000) and Zhang (2002). In their models, the acceleration of traffic depends on the speed gradient u_x instead of the density gradient k_x .

Nonequilibrium models allow traffic states to deviate from the FD and produce hysteresis loops in flow-density or speed-density plots (e.g., Jin and Zhang, 2003), which are often observed in such plots of real life traffic. Unlike the LWR model, which always produces stable traffic flow patterns, the nonequilibrium models can produce unstable traffic flow patterns due to the interaction between relaxation and anticipation (e.g., Zhang, 1999). While the nonequilibrium models provide a more realistic description of traffic flow (e.g., Fan and Seibold, 2013; Fan et al., 2017), solving it is more involved than solving the LWR model (e.g., LeVeque, 1992; Zhang, 2001), and are not as widely used as the LWR model in practice.

Heterogeneous Traffic Flow

When traffic comprises quite different vehicles/drivers, such as cars and trucks, extension of the LWR model to address heterogeneous traffic is necessary. In traffic flow, heterogeneity can be a result of different vehicle maneuverability (e.g., passenger car vs. truck), level of automation (e.g., human-driven vehicles vs. autonomous vehicles) or driving style (e.g., aggressive vs. timid drivers).

Most existing models consider two classes of vehicles, typically passenger cars and trucks. In recent works, attentions are paid to modeling the mixed flow of human-driven and autonomous vehicles. A flux function is defined for each class, and the interactions of different traffic streams are captured through coupling of the two flux functions, $Q_1(k_1, k_2)$ and $Q_2(k_1, k_2)$. This leads to a general formulation of two-class traffic flow models,

$$U_t + Q(U)_x = 0 \quad (32)$$

where $U = (k_1, k_2)$, and $Q = (Q_1, Q_2)$ is the flux pair. In the vector notation, its form resembles the single-class LWR model. However, its properties and solution can be much more complex.

The flux pair may be specified through either a descriptive or a behavioral approach. The descriptive approach prescribes flux functions based on assumptions of aggregate flow attributes, for example, regimes when the two traffic streams synchronize speed and traffic volumes. Many earlier multi-class traffic flow models adopt this approach (see e.g., [Wong and Wong, 2002](#)). The major limitation of this approach lies in the negligence of detailed driver/vehicle interactions as well as the role of lane use.

In contrast, the behavioral approach explicitly considers interactions of different vehicle classes and lane settings (such as special lanes) and leverages such information to construct the pair of fluxes. The construction usually starts from nominal fundamental diagrams each class is endowed with. This procedure can lead to more interpretable heterogeneous flow model, but the flux pairs usually do not have closed-form expressions, unless in simple cases. As an example, [Daganzo \(1997\)](#) used this approach to model two streams of traffic on a road with a special lane. Another type of models that share similarities with both descriptive models and behavioral models. These models incorporate behavioral rules for drivers/vehicles, such as Wardrop's User Equilibrium principle ([Wardrop, 1952](#)), but do not model lane use policies or detailed lateral distribution of drivers/vehicles across lanes. A representative model in this category is [Logghe and Immers \(2008\)](#).

Comments on the Piped Traffic Flow Models

The piped traffic flow models are among the most versatile and powerful traffic flow analysis models developed to date. They provide enough detail to describe and model the important features of traffic flow, such as congestion formation, propagation, and dissipation, and the workings of bottlenecks, without the need to model thousands or millions of vehicles in a city individually. The numerical schemes developed to solve these models, coupled with junction models (e.g., [Daganzo, 1995a](#); [Lebacque, 2005](#)), form the core of flow rather than vehicle based network traffic simulation models. As in a microscopic traffic simulation, flow-based simulations can be used to obtain travel times, travel delays, VMTs and VHTs using the methods described in Section Basic Tools and Definitions. Unlike in a microscopic traffic simulation, only a limited number of parameters need to be calibrated (for example, the location-dependent $FD-Q(k, x)$ is the only function to calibrate in the LWR family of models) in a flow-based simulation. Flow based simulation can provide good estimates of the performance measures such as travel times/delays, VMTs and VHTs. On the other hand, vehicle based simulation provides more accurate estimate of fuel use, emissions, and individual delay due to their finer granularity. Which simulation to use in a specific application depends on the size of the network, the level of detail one needs to model the traffic environment, the types of performance measures one is interested in, and the amount of labor and financial resources at hand for the application.

Reservoir Traffic Flow Models

The basic spatial unit of analysis in the models presented in the previous sections is a road segment or junction. Using these models to assess how well city traffic moves would require the modeling of each road and junction in the city. Yet in some occasions there is a desire to know how well a city's traffic moves on average without zooming in to each road, just like a physician takes the pulse and/or temperature of a person to get the first impression of the health of a person without X-rays or MRIs. The first known effort towards this is due to [Smeed \(1966\)](#), who investigated the capacity of traffic entering the city center (Q_c) as a function of the area of the city center (A), the proportion of the area devoted to roads (f), and the capacity of the roads (Q_r):

$$Q_c = \alpha f Q_r \sqrt{A} \quad (33)$$

where α is a parameter specific to a city. A subsequent effort by [Thomson \(1967\)](#) to examine the average speed and flow data collected over the center of London yields a linear speed-flow relation:

$$U = U_0 - bQ \quad (34)$$

and found that the speed U_0 for inner zones of London is lower than that for the outer zones of London.² Replacing U with Q/K in the above equation we get the town center flow-density FD:

$$Q = U_0 \frac{K}{1 + bK} \quad (35)$$

This is the first known macrofundamental diagram (MFD) of city traffic. Yet since dQ/dK is positive, that is, flow always increases with density, this MFD is not suitable to describe town traffic under highly congested situations. It is almost four decades later that more extensive data were collected and a more complete picture of MFD is revealed. [Geroliminis and Daganzo \(2008\)](#) showed the MFD of town traffic resembles that of a road, with a concave shape where flow reaches zero when traffic is jammed throughout the

² Here we use upper case letters to denote that these variables are for a town center, to distinguish them from those of a specific road location.

city. From a quite different approach, [Herman and Prigogine \(1979\)](#), based on the gas-kinetic theory of traffic flow ([Priogine and Herman, 1971](#)), stipulated that the average speed of a town's traffic is a function of the fraction of moving or stopped vehicles at a given moment, and carried out simulation studies to verify this so-called two-fluid town traffic model with good accordance (e.g., [Williams et al., 1987](#)).

Both empirical evidence and theoretical analysis strongly indicate that for the town center with densely laid roads with similar characteristics, a macro fundamental diagram, $Q^*(K)$ exists. Suppose the amount of the flow reaching their destinations inside the town center is proportional to $Q^*(K)$: $rQ^*(K)$, with r being the percentage of the flow reaching their destinations, and that the traffic generated from within the town center and from outside the town center is $Q(t)$, one can develop a reservoir like model

$$L \frac{dK}{dt} = Q(t) - rQ^*(K) \quad (36)$$

where L is the total length of the roads inside the town center. This model tells how the average density and speed in the town center evolves over time without the need to study how traffic evolves in each road segment and at each junction. An important feature of this town traffic model is that, due to the concave shape of the MFD and the existence of an absorbing state at $K = K_j$, the town traffic has a tendency to gridlock after the density (or the total number of vehicles inside the town) passed a critical value (e.g., [Daganzo et al., 2011](#)).

Remarks and Further Reading

This chapter presented some of the main traffic flow models developed to date, from static to dynamic, and from individual vehicles to traffic in an entire town. Due to space limitations, several aspects of traffic flow analysis was not discussed in this chapter. The first is the role of lane use and lane changing in particle tracing traffic models. Interested readers can refer to [Zheng \(2014\)](#) for a recent review on this topic. The second is the role of randomness in traffic flow dynamics, which has been shown to play a significant role in causing traffic instability (e.g., [Tian et al. 2019](#)). Last but not least, the emergence of connected and autonomous vehicles (CAV) is likely to affect traffic flow analysis profoundly. For example, the communication between vehicles enable information sharing with neighboring vehicles and beyond, so vehicles can respond to traffic conditions both behind and ahead of them in a greater range beyond their immediate neighbors, and can follow each other more closely than human driven vehicles. This means that for CAV traffic both the capacity and wave speeds can be higher. A more significant challenge lies in modeling the mixed flow containing both human driven vehicles and CAVs. Since CAVs are still in their infancy, limited data are available to the transportation research community to understand the interactions between human driven vehicles and CAVs. Much research is anticipated in the development the CAV technology, its role in transportation, and the flow analysis tools to model traffic mixed with CAVs and human driven vehicles in decades to come. Since this is a rapidly developing area of research, there is no definitive reference for this topic and readers are recommended to read the latest articles in journals and conference proceedings such as the Transportation Research B & C, Transportation Science, the IEEE Transactions series, and Transportation Research Records.

Biography

H. Michael Zhang is a professor in the Department of Civil and Environmental Engineering at the University of California Davis. He is also a faculty member in the Graduate Programs of Applied Mathematics and Transportation Technology and Policy at UC Davis. His research focuses on applications of systems theory to transportation systems analysis and operations. Specific topics include traffic flow theory, traffic control, traffic safety, transportation network modeling, and intelligent transportation systems such as connected and autonomous vehicles. He is an area editor of the Journal of Networks and Spatial Economics and Associate Editor of Transportation Research, Part B: Methodological and Transportation Science. His awards include an NSF CAREER (2000) and a best paper award from Vehicular Communications (2018), an Elsevier journal. He received his BS degree in Civil Engineering from Tongji University (Shanghai, China) and his MS and PhD degrees in Civil Engineering from University of California Irvine. Prior to his UC Davis appointment, he has taught at the University of Iowa from 1995 to 1998.

Jia Li is a research assistant professor at Texas Tech University. His research focuses on the intersection of traffic flow theory, transportation systems modeling, and connected and autonomous vehicles. He received his PhD in Transportation Engineering from University of California Davis in 2013, and conducted his postdoctoral research with Professor Michael Walton at the University of Texas at Austin from 2013 to 2016.

Introduction and Motivation

A new era of connected and autonomous vehicle (CAV) technology is emerging due to rapid advancements in communication technology, machine learning and artificial intelligence, vehicle-based sensing, and computation. However, as autonomous vehicles near commercial availability, there exists much uncertainty about the implications of this transformative technology including the ownership costs, mode of deployment (shared versus private), adoption rate and technical capabilities, which will all influence potential changes in travel behavior, mobility, and energy outcomes. National, regional and local governments are facilitating research to develop a better understanding about potential outcomes of CAV in terms of travel demand, regional mobility, energy use, emissions, and so on. This has led to numerous studies looking at different aspects of CAV short- and long-term outcomes, by both adapting traditional transportation models and developing new transportation simulation techniques.

This article reviews research that models CAV from the following perspectives: (1) modeling demand impacts, (2) modeling land use and other long-term changes, (3) modeling traffic flow impacts, and (4) modeling system control impacts. For each area, a general discussion about the plausible impact is presented first. A review of pertinent modeling studies, findings and research gaps for each perspective follows.

Demand Impacts of CAVs

The automation aspect of CAVs is expected to drive changes in travel behavior through the elimination of the human driver, as identified in multiple high-level analyses, including (Brown et al., 2014). This has the possibility to increase travel demand in multiple ways, including expanding mobility, inducing additional travel demand, changing long-term travel patterns and altering land use. Mobility could be expanded in two ways. First, CAV offers a new and convenient mobility option that operates like privately owned automobiles to individuals who currently are underrepresented in the driving population: persons with disabilities, minors, elderly citizens, and so on. As such, CAV is likely to lead to increased travel by these groups. In the same vein, elimination of driving duties can alter the experience of driving altogether for individuals that currently drive. By reducing or removing the need for driver attention (in partial and full automation, respectively), the experienced burden of travel in an automobile can be substantially reduced for drivers. This can lead to a reduced disutility of travel, which is further enhanced by the ability to engage in productive and relaxing activities in lieu of driving. For drivers, therefore, mobility is expected to expand due to a reduction in value of travel time (VOTT). This in turn could induce greater travel demand, with people making more trips and/or accessing more distant but more desirable activity locations. This would result in longer travel durations and increased vehicle miles travelled (VMT). However, travelers initially may be unfamiliar with or apprehensive about CAV technology, so they may attach high VOTT to CAV travel at first. There is also much debate about the deployment mode of the CAV technology: a shared fleet system versus privately ownership. While shared AV is more favorable from the VMT and energy use perspective, private AV can generate a notable increase in VMT due to low marginal cost and increased empty miles traveled. However, private ownership of CAV can also be influenced by its income generating potential through participation in the sharing economy and thereby minimizing negative externalities. Addressing these factors is important for assessing travel demand impacts of CAV.

Attempts to investigate the impacts of CAV or shared automated vehicle (SAV) systems on travel behavior range from simple rule-based models to complex agent-based and integrated activity-based and dynamic traffic simulation frameworks. On the simpler end,

several studies have used methods including cross-classification based on demographic characteristics or assignment of fixed demand with a simplified grid network to study the impacts of CAV. More detailed transportation modeling efforts have paired regional demand inputs with dynamic traffic assignment. Multiple studies using a variety of transportation modeling platforms for various cities, including Austin, Chicago, Berlin, Zurich, and others have explored the impact of SAV fleets for various fleet sizes and potential replacement rates to serve existing demand. In general, these studies predict that each SAV could replace between 5 and 12 privately owned vehicles (Bischoff and Maciejewski, 2016; Fagnant and Kockelman, 2014). These detailed analyses also generally predict that SAV systems will generate a substantial increase in overall travel largely due to vehicle repositioning and pickup trips. To date, most studies of SAV on a regional level have used fixed demand inputs or have allowed some characteristics of demand, such as mode choice, to change. The induced demand effect in such studies, then, is limited to that derived from mode changes and route assignment.

Other studies have explored modifying existing trip-based or activity-based travel demand models to simulate one or more aspects of CAV deployment. In activity-based models, the VOTT change effect can often be introduced by modifying travel time parameters in various choice modeling components. Enhanced mobility can be included in the mode choice process by allowing nonlicensed drivers to utilize privately owned AVs or to have AVs perform household tasks such as escorting children. Multiple examples of existing activity-based models at MPOs being modified in this manner to explore some CAV impacts have been observed in the literature. Agent-based models are more frequently being used to explore CAV impacts as well. These share many features of activity-based travel demand models, with more emphasis on modeling agent interactions in the system, including persons, households, vehicles, system managers, and fleets. These types of models allow the representation of the interactions between agents in the system, which is especially relevant in exploring CAV impacts on travel demand and traffic flow and the resultant feedbacks (Auld et al., 2018).

From studies observed in the literature, it is found that most of the research explores the impact of private or SAVs with very few studies investigating the impact of both together (i.e., mixed modes of AV operation). There is also little focus in current transportation models on the connectivity aspect of CAVs. Moreover, the studies that do exist have had to make critical assumptions about the travel characteristics to enumerate different future scenarios under the market penetration of autonomous and connected vehicles. Major assumptions are made regarding road capacity (+10% to +100%), VOTT (−20% to −100%), parking cost (−50% to −100%), market penetration of private AVs (+7.5% to +100%), operating cost of shared AVs (\$0.13/mile to \$1.65/mile), travel time increase due to sharing (+20% to +50%), and replacement of vehicle trips by AVs (+1.3% to +100%). Consequently, the outcome of different studies seems to vary considerably depending on the range of assumptions.

To offer insights into system performance impacts of CAV, existing studies typically report the change in vehicle miles (kilometers) traveled (VMT/VKT), vehicle hours traveled (VHT), and shift in modal share in response to CAV. Studies have generally predicted that VMT/VKT will increase, with values ranging up to 79% for private AV (Auld et al., 2018). Reported empty miles traveled due to zero occupancy vehicle (ZOV) trip ranges up to 16% (Loeb et al., 2018). Some studies report reduction in vehicle hours traveled (VHT) up to 41% (Childress et al., 2015), largely due to assumed increases in road capacity. In contrast, some research shows a decrease in VMT when all private vehicles are replaced by a SAV system with high operating costs, while generally most studies of SAV systems show overall VMT increases due to repositioning moves.

In terms of mode shifts, the studies report mixed outcomes depending on the assumptions regarding private vehicles. When it is assumed that private vehicle ownership and utilization will still exist, transit mode share generally decreases depending on location, quality of existing transit service, and assumptions about VOT in AVs. Studies that instead assume complete disposal of private vehicles with replacement by SAV systems find an increase in transit and walk share.

Research gaps in modeling travel demand impacts of CAV pertain mainly to underlying assumptions that are used in analysis and how the assumptions are developed. A review of transportation demand modeling studies reveals widespread use of simplified assumptions regarding future scenarios. Almost all the studies assume a fixed rate for household vehicle disposal irrespective of household location and SAV levels of service such as operating cost and wait time. Some studies do not consider any changes in activity participation for different future CAV scenarios resulting in fixed demand for all future conditions. Others do not consider the trade-off in level of service (LOS) between different transport modes, instead assuming a fixed modal share or rule-based assignment to different transport modes. Simplification in traffic assignment is also often seen, with studies as using an idealized network. Most have also used unimodal network assignment instead of multimodal assignment. Finally, many studies only focus on one specific effect of CAV, such as the effect of dynamic ride sharing. However, as transportation is a complex adaptive system with many potential ownership and deployment possibilities as well as multiple interactions between demand, vehicle operation, system operation, traffic flow, and so on, focusing on only one aspect can often lead to uninformative or misleading results.

Land Use and Other Long-Term Impacts of CAV

CAV deployment is expected to trigger changes in longer term choices due to changes in accessibility and reduction in VOTT. Changes in accessibility might influence people to choose different home and workplace locations, creating shifts in population density. Also, assuming that inter- and intrahousehold sharing of CAVs reduces parking demand, opportunities for new

infrastructure/land use development may be created. Changes in accessibility also have the potential to lead to firm relocation, which would also result in new land use patterns.

Very few studies have attempted to study the long-term impacts of CAV. Some studies have used land use and transportation interaction models to study the impact of CAV on transportation infrastructure and urban form. Typically, these tools use discrete choice models to (re)distribute population across the study area as a function of accessibility to employment and four step models for simulating transportation system impacts. Some researchers have used macroeconomic models to understand the impacts of private and shared automation on land use. Macroeconomic formulations model consumers' choice of household location, job location, and commute mode using discrete choice specification. One distinguishing feature of the macroeconomic formulations is that they ensure price equilibrium for the residential market. Integrated SAV simulation and disaggregate choice models for residential and firm locations have also been used to study the impact of CAV on parking and urban sprawl, where SAV operation is usually simulated as discrete event engine and residential/firm location choices are generated using discrete choice models. Some researchers have used macroscopic transportation simulation tools to investigate the impact of AV on accessibility. Initial findings from the research on long-term impact of CAV can be grouped into three main categories: change in parking requirements, change in (sub)urban population, and change in land use.

Assuming that SAV systems serve all or part of current travel demand, studies predict a reduction of up to 90% in parking space requirements (Bischoff and Maciejewski, 2016). The estimated reduction in parking space requirement is much smaller assuming private AV ownership, with several studies showing less than 10% reduction, although this could be changed if dedicated AV parking facilities for private AV were introduced (Zhang et al., 2018).

Private AV ownership is predicted to increase accessibility and consequently population in the suburban and rural areas. Studies predict around a 5% increase in suburban population and a similar reduction in the urban population due to increased accessibility of the suburban areas resulting from private AV ownership. Mixed effects are reported for SAV scenarios. According to some studies, SAV has the potential to curb urban sprawl. However, depending on the assumption, SAV also has the potential to increase urban sprawl. For example, an assumption that all private vehicle trips are replaced by SAVs generates a 4% increase in urban population and 3% reduction in suburban population. Efficient public transportation systems complemented by SAV can increase urban population by 3% and decrease suburban population by the same margin.

Land-use changes are also expected to be driven by CAV deployment, and have often been studied with dedicated land use models, such as UrbanSim or others. Studies have indicated an increased trend of deindustrialization in urban areas, with changes in the job density based on the type of industry. Such predictions of impacts in future scenarios are sensitive to the assumptions that are made. Uncertainty about these assumptions (such as shared versus private ownership of autonomous vehicles, changes in VOT, and level of service characteristics of SAVs) currently forms a major hindrance to predicting future impacts of CAV. Also, many of the studies assume no change in the short-term travel behavior—in particular, several studies assume that activity patterns do not change. This is a major limitation since activity patterns in general probably will experience noticeable shifts, as the new mobility options alter trip making tendencies and hence activity patterns of those who currently do not drive as well as those who currently drive. Also, studies that focus on changes in short-term decision-making use simplified inputs such as grid networks instead of detailed, local transportation network, which limits the realism of the analysis.

Modeling Traffic Flow Impacts of CAV

Along with inducing changes in travel demand, the increase in vehicle automation and communication capability enables a plethora of applications that can affect different aspects of traffic flow, that are also critical to transportation system modeling. Depending on the vehicle capability and the infrastructure available, such systems can improve safety, increase traffic capacity (throughput), and reduce energy consumption and emissions. A summary of the implications of CAV technology on traffic flow is provided below. Readers can refer to Diakaki et al. (2015) for a thorough description of each.

- **Adaptive cruise control (ACC):** Adaptive cruise control is a low-level automation that allows vehicles to maintain a desired speed while maintaining a safe distance between successive vehicles. ACC can increase roadway capacity by reducing headway as the penetration rate of ACC increases. Increased capacity of up to 20% at high penetration rates is predicted;
- **Cooperative Adaptive Cruise Control (CACC):** Adding to the functionalities of ACC, CACC systems exchange information with neighboring vehicles to avoid traffic oscillations following accelerations and decelerations of the lead vehicle. Several studies have indicated that CACC can increase capacity up to 60% (Shladover et al., 2012). The communication also improves string stability (i.e., small oscillations are not amplified), which can further lead to energy savings.
- **Cooperative Merging:** vehicles assist drivers or perform lane-changing maneuvers leveraged by vehicle-to-vehicle (V2V) communication between the maneuvering vehicle and vehicles in the target lane. It can reduce travel times and energy consumption, but the extent of reduction is unclear.
- **Eco (Green)-driving:** Eco-driving encompasses a variety of strategies that attempt to reduce fuel consumption and greenhouse gas emissions without affecting overall travel times. Different levels of automation and connectivity can improve eco-driving benefits. In general, the vehicle gathers information of an expected future driving horizon through sensors, V2V data (e.g., current speeds of preceding vehicles), vehicle-to-infrastructure (V2I) data (e.g., green and red times of traffic lights) then plans vehicle controls to

reduce energy consumed along the trajectories. Several studies have found energy savings of up to 20% through the utilization of eco-driving.

- **Platooning:** This application attempts to keep multiple vehicles closely spaced for convenience, safety and fuel efficiency, primarily through aerodynamic drag reduction (of up to 50% according to some studies).

There is considerable uncertainty regarding the estimated benefits of CAV to traffic flow, as field data from such applications are limited. Most estimates are obtained through microsimulation by adding the specific driving behavior (car-following and lane-changing) into existing microsimulation packages. Additionally, the communication network and message exchanges between the vehicles are sometimes considered. Impacts are assessed by varying the share of vehicles with the specific capability (e.g., CACC, eco-driving, etc.).

Although microsimulation models can be used to analyze CAV impacts, they are usually limited to a small region as computational cost prevents application in a broader area. For this reason, several mesoscopic and macroscopic models have been developed to evaluate the impacts of CAVs at an aggregated level. The most common approach involves deriving the Lighthill–Witham–Richards (LWR) model and its popular discretizations such as the Cell or Link Transmission Models. The fundamental diagram is modified based on the share of enabled vehicles within the cell or link in addition to the density.

The market share-dependent fundamental diagram can be obtained in different ways. One can derive baseline fundamental diagrams from data as in common practice. For increasing technology penetration, a steeper derivative is assumed for the congested segment of the fundamental diagram, reflecting a smaller gap between enabled vehicles. Alternatively, fundamental diagrams for varying penetration rates can be obtained through microsimulation runs with different penetration rates of automation technology (Kun Li and Ioannou, 2004; Shladover et al., 2012). Several studies have considered a two-class cell transmission model for modeling mixed traffic. These models maintain a good compromise between computational time and accuracy and are suitable for large-scale metropolitan area analysis, especially for capturing the interaction between demand and supply (capacity).

In summary, increased level of automation and increased penetration can lead to improvement in traffic flow for similar demand levels, but the extent of the benefits is uncertain due to different aspects. First, while the traffic dynamics are somewhat well understood for the current conditions (i.e., human-driven vehicles) and for 100% penetration of CAV, the benefits for intermediate level of automation are uncertain. This is primarily due to the lack of data for mixed traffic conditions and for different vehicles with variable levels of automation and enabled features. Second, the coordination among vehicles and infrastructure depends on whether all different equipment (actuated signals, vehicles from different OEMs, sensors, etc.) can effectively communicate among themselves. Finally, some aspects of AV traffic flow such as automated merging have been largely understudied to this point.

System Control Under CAV

As discussed above, the presence of CAV features can improve traffic flow through modification in the driving behavior and communication exchange with surrounding vehicles. However, these are local impacts with uncoordinated control. As is well known in the transportation literature, a local change can trigger downstream impacts in the network because of changes in the route, mode and departure time choices. This motivates the development of management and control strategies for CAVs to generate benefits at the system level.

The key aspect of management and control at the system level is coordinated decision-making by various elements of the infrastructure or by a centralized authority, in contrast to decisions being performed only by individual vehicles. Note, however, that this level of coordination does not forfeit the benefits provided by increasing automation level; it further improves their benefits by coordinating vehicle level control with infrastructure decisions. Some potential applications discussed in the literature include:

- **Eco-approach and Departure (EAD):** The eco-driving approach can be extended by enabling the infrastructure to exchange information with individual vehicles. A recent field test (Hao et al., 2014) in which the actuated signal communicates Signal, Phase and Timing (SPaT), a system within the vehicle computes optimal speed trajectory and provides a suggested speed to the driver. They found an energy reduction of about 6%. Microsimulation studies have found energy savings of around 20%.
- **Fully Automated Intersection:** A new intersection timing is based on the concept of allocating time to specific movements for a scheme in which vehicles are coordinated to cross the intersection at specific intervals, thereby avoiding stops while maintaining safety. This approach is often referred to as a signal-free scheme, and can give travel time reduction up to 50% (Malikopoulos et al., 2018).
- **Charging Scheduling:** As the share of electric vehicles increases, an important element is to determine when and where to charge vehicles (including CAV) and at what price. Through V2I, the infrastructure can mediate this interaction using information on the state of charge, location, and intended trip schedule of electric vehicles. Congestion pricing or tradable networks help to constrain increases in congestion by charging a higher fee in periods of high demand. Alternatively, the demand can be limited by a fixed quota of road usage given to citizens that could trade these permits based on their necessity.

In summary, different infrastructure-based management and control strategies can be leveraged by connected vehicles. It is worth mentioning that improvements can also be achieved on the current traditional Intelligent Transportation Systems (ITS) applications such as traffic signal control and ramp metering. The impacts of the various strategies will depend on technological aspects, such as

automation levels, as well as market penetration and deployed infrastructure. The potential of these strategies is also dependent on the CAV adoption and household AV ownership.

Conclusion

Understanding the implications of CAV deployment on the transportation system is still in its infancy. There exists much uncertainty about how CAVs will be deployed, the strategies that will be used for their operation, the public's willingness to adopt the technology, and consequent impacts for both individuals and the system as a whole. Moreover, a lack of data regarding these and other elements has caused heavy reliance on assumptions to produce plausible future scenarios. The outcomes of the studies vary considerably depending on the assumptions used and their ranges, which vary widely across studies. Implications for travel behavior appear to be much less certain than implications for network flow. Another issue is that although CAV is likely to have numerous effects that interact with one another, many studies rely on relatively simple models that focus only on a limited number of system subcomponents. However, a few studies have used agent-based models with dynamic traffic assignment to generate tenable results at the system level, demonstrating that sufficiently comprehensive analytical methods are within reach. As the deployment of the technology becomes imminent, a better understanding about the assumptions will be needed to narrow down the plausible implications and to help formulate effective policies regarding CAV operation.

Biography

Annesha Enam is currently serving as a postdoctoral appointee at Argonne National Laboratory where she is working on travel behavior modeling with focus to emerging and disruptive technologies. Annesha Enam completed her undergraduate and master's degree from Bangladesh University of Engineering and Technology (BUET). She completed her doctoral studies from University of Connecticut (UConn), USA in activity and travel behavior modeling. Her dissertation research was awarded the 2017 CUTC Charley V. Wootan Memorial Award by the Council of University Transportation Centers in the USA. Her research interests include econometric modeling of choice behavior, activity time use and well-being, transportation planning, use of data mining and machine learning methodologies for understanding choice behavior.

Felipe de Souza is a Postdoctoral Appointee in the Vehicle and Mobility Systems Group at Argonne National Laboratory. He received a bachelor degree in Control and Automation Engineering and master of science in Systems Engineering, both at Universidade Federal de Santa Catarina, Brazil. He completed his doctoral studies at University of California, Irvine in Transportation Systems Engineering. His main research interests are traffic modeling and control, transportation systems simulation, and fleet dispatch optimization.

Monique Stinson is a Computational Transportation Scientist at Argonne National Laboratory where she is developing agent-based models of freight transportation and behavioral models of passenger transportation. Her research covers both commercial markets as well as interactions between commercial and passenger markets, including aspects related to AV and SAV adoption in a Sharing Economy context. Monique is a member of the Freight Planning and Logistics Committee and a friend of other freight and passenger behavior committees. She earned her Bachelor of Science and Master of Science degrees in Civil Engineering from the University of Texas at Austin, and is currently earning her PhD in Civil Engineering at the University of Illinois at Chicago.

Omer Verbas is a Computational Transportation Engineer in the Vehicle and Mobility Simulations Group in the Center for Transportation Research at Argonne National Laboratory. His primary research areas are in transportation network modeling; multimodal routing, assignment, and simulation; and transit network design and scheduling. He completed his doctoral studies at Northwestern University in 2014 under the supervision of Prof. Hani S. Mahmassani with whom he worked as a Post-Doctoral Researcher until 2016. Prior to joining the PhD program at Northwestern, he received his Master of Science degree in Transportation Engineering from Istanbul Technical University.

Joshua Auld is a Principal Computational Transportation Engineer in Argonne's Vehicle and Mobility Simulations Group, and technical manager of transportation systems simulation. He completed his Doctorate in August 2011, in the Civil and Materials Engineering Department of the University of Illinois at Chicago with a concentration in transportation. He has experience in a variety of areas in transportation, with a primary focus on dynamic activity-based travel demand models and the interactions between travel demand and intelligent transportation systems operations. He is a member of the TRB Travel Forecasting Resource and Transportation Demand Forecasting Committees.

Introduction

It is undeniable that the world's transportation landscape has undergone substantial changes in the 2010s, one of the most notable ones being the birth and growth of ride-hailing services provided by companies such as Uber, Lyft, Didi, and Ola (often referred to as transportation network companies or TNCs). Ride-hailing has been referenced by several different terms, including ride-sourcing, ride-splitting, ride-sharing, real-time ride-sharing, ride-booking, parataxis, on-demand rides, and e-hailing. These services can be classified as being a form of mobility-on-demand and as being part of the larger mobility-as-a-service trend, which allows individuals to purchase mobility by the trip instead of owning (and using) their own vehicles.

Simply put, ride-hailing companies provide a platform that connects willing drivers and riders. These services take advantage of the popularity of smartphones and their embedded technology to provide users with a reliable on-demand door-to-door transportation service that is usually cheaper than traditional taxis. Another key element that appeals to users is the seamlessness of the experience: rides can be requested (hailed), tracked, and paid using one single smartphone app (Dias et al., 2017). Ride-hailing companies usually offer multitiered services to their users, ranging from cheaper services with regular vehicles to more premium services with luxury vehicles and professional drivers. This provides more options to potential riders based on their need for comfort and sensitivity to price. Recently, most ride-hailing companies have also made a notable new addition to their service rosters: pooled rides, sometimes referred to as shared rides or ride-splitting. This service offers ride-hailing users a discount if they accept sharing their rides with other passengers who have similar pick-up and drop-off locations, further enhancing the ride-hailing option set. Further, typical taxis have fares calculated using a fixed formula based on mileage and time which can vary by time of day. Conversely, in the context of ride-hailing, fares are usually multiplied by a "surge" during periods of high demand of ride-hailing. Ride-hailing companies claim this is done to moderate demand and to stimulate an influx of drivers to serve high-demand locations. Also of note is that Uber has recently started engaging in "route-based pricing," in which they charge customers based on what an Artificial Intelligence algorithm predicts the potential riders are willing to pay, instead of its older pricing scheme which only involved mileage, time and surge multipliers (Newcomer, 2017).

Ride-hailing services differ from classic taxis in a few key aspects in addition to their cost/price structures. The first difference has been the center of several clashes between the ride-hailing and taxi industries: the issue of licensing and regulation. In most cities, the taxi industry is heavily regulated: drivers need to have city-issued permits, some form of insurance, and vehicles need to be inspected on a routine basis. Ride-hailing companies, on the other hand, while claiming to uphold high driver and vehicle quality standards, generally do not need to adhere to the same standards of regulations. There have been a few exceptions, as in the city of Dusseldorf in Germany, where after ceasing operations in 2015 due to regulatory disputes, Uber relaunched their services in late 2018 after agreeing to employ only professional drivers (see Bershidsky 2018). Another difference between the two services is that ride-hailing vehicles are typically hailed exclusively through smartphone apps, while traditional taxis can be hailed on the street and, in some cities, through smartphone apps as well.

The dramatic exponential growth of ride-hailing services is often depicted using a now famous statistic: since the day it was created, it took Uber 6 years to serve its one billionth ride, but only 6 more months to serve two billionth. Just two years after that, in 2018, Uber reported serving its 10 billionth ride (Kokalitcheva, 2016; Uber, 2015, 2018). An interesting summary of the company's timeline can be found in Hartmans and Leskin (2019).

A comprehensive literature review of all aspects surrounding ride-hailing services can be found in Wang and Yang (2019). In this paper, we will present the reader with a short summary of some of the main topics surrounding ride-hailing and how its use has been studied in recent years.

Disruptiveness

Since their creation, ride-hailing companies have disrupted the transportation industry similarly to how Amazon and AirBnB have, respectively, disrupted the retail and hotel industries. This disruption has brought multiple positive changes, such as increased accessibility in transit deficient locations, job opportunities to lower-skilled and unemployed individuals, opportunities for people to earn money “on the side” by driving for ride-hailing companies outside of their regular working hours, and giving passengers a transportation option that has the same comforts as private automobiles and is slightly cheaper (and often more convenient) than traditional taxis.

This disruption, however, can have (and has had) unintended negative consequences. One such example is New York City’s taxi industry and its medallion system. “Medallions” are city-issued licenses to operate taxis and hail rides. At the time of the medallion system’s creation in 1937, each of the city’s 16,900 medallions cost \$10 (Van Gelder, 1996). As time passed, the number of medallions remained almost constant while their cost climbed, reaching \$100,000 in 1985 and \$200,000 in 1997, until they reached their peak price of \$1.3 million in 2014 (Hu, 2017; Rosenthal, 2019). In 2015 just 4 years after the introduction of ride-hailing services in New York City, the number of Uber cars was already larger than the number of licensed taxis (Licea et al., 2015). Shortly thereafter, medallion prices fell dramatically, reaching prices as low as \$160,000 in 2018, sending thousands of people into debt and even leading some to commit suicide (Fitzsimmons, 2018; Hu, 2017; Rosenthal, 2019; Walker, 2018). It has been defended that the actual effect of ride-hailing companies was minimal, reducing taxi pickups by only 10%, and that this was simply the small nudge needed to burst a market bubble that was already long overdue (Rosenthal, 2019). Regardless of the actual magnitude of ride-hailing companies’ impacts, it is clear that these services have become an important segment of our transportation system and deserve to be closely studied.

Regulation

Another important aspect about ride-hailing companies and the services they provide is centered around the issue of regulations. Companies such as Uber and Lyft have, for the most part, not been subject to the same regulatory requirements that typically apply to transportation services such as taxis and limousine companies. Taxi driver demonstrations demanding law-makers to enforce regulations on ride-hailing companies and to ensure fair market conditions have been a common occurrence around the globe (Che, 2015). In most cases, ride-hailing companies have been successful in their push back efforts and have been able to avoid new regulations. A good example of such efforts is the case of Austin, Texas. Uber and Lyft (the two biggest ride-hailing companies in the city) spent approximately \$8 million to support Proposition 1, a bill that prohibited the city from requiring ride-hailing companies to perform fingerprint background checks on their drivers. In May 2016 the bill was put to public vote and was rejected by 56% of voters, making it clear that Austin’s residents wanted ride-hailing companies to perform the background checks on their drivers. Three days after the vote’s results were published, Uber and Lyft expressed disappointment with the political defeat and officially ceased operations in the city. The companies then decided to focus their lobbying efforts at the state level: approximately one year later, in a 21–9 vote, the Texas Senate approved a statewide bill that eliminated local ordinances for ride-hailing companies (such as Austin’s fingerprint background check requirements), effectively overruling the decision Austin’s residents’ has voted on just one year prior. Uber and Lyft then relaunched their operations in Austin mere hours after the Texas Governor, Greg Abbott, signed the bill into law two weeks later (Herskovitz, 2017; Lee, 2017; Mekelburg, 2016; Samuels, 2017; Office of the Texas Governor, 2017; Wear, 2017).

Travel Demand

Due to the ever-growing global presence of ride-hailing companies, several studies have attempted to study this newcomer in the transportation landscape. In this section, we briefly cover some of the research efforts that have tried to understand the characteristics of ride-hailing users and their trips.

Despite the dramatic growth in the demand for and usage of ride-hailing services, their mode shares are still quite small in almost all the cities in which they operate. Most recent travel surveys in the United States, including the 2017 National Household Travel Survey and a number of metropolitan area travel surveys (e.g., San Diego, Sacramento, Phoenix), indicate mode shares of under one percent for ride-hailing services (Federal Highway Administration, 2017; RSG Inc., 2018). Even though ride-hailing services may have generated some new latent demand and reduced some personal automobile travel, particularly in a few dense urban markets (Lavieri and Bhat, 2019a), some authors defend that they have served as a substitute to transit and traditional taxi services (Schaller, 2018), both of which already had very low mode shares in most American cities. Meanwhile, other researchers have found that ride-hailing services actually complement transit services (Zhang and Zhang, 2018). Another such example is Babar and Burtch (2017), who found that rail-based and long-haul transit services, such as subway and commuter rail, are also associated with increased ride-hailing use. It seems that, at least for the time being, ride-hailing will continue to represent only a small fraction of all trips unless ride-hailing companies start making significant impacts on individuals’ current personal vehicle travel trends. Regardless of their small mode shares, metropolitan planning organizations (MPOs) and transportation agencies around the world still need to

consider ride-hailing services in their modeling efforts because they might have significant implications for future transit investments, parking capacity needs, curbside management, safety, and vehicle miles of travel (Dias et al., 2019).

Unfortunately, there are only a handful of publicly available data sources on ride-hailing usage. Due to understandable privacy and competitiveness issues, ride-hailing companies are quite reluctant to share any kind of ridership data. This has lead researchers and transportation professionals to rely on secondary data sources (e.g., MPO's household travel surveys that have some ride-hailing specific questions) and to develop their own surveys to characterize ride-hailing use, such as Lavieri and Bhat (2019a) and Rayle et al. (2016). Regardless of their data-related difficulties, these research efforts have provided valuable insights into understanding how people interact with ride-hailing services.

The pioneering works in the behavioral analysis of ride-hailing revealed that the service's users tend to be younger, more educated, live in urban areas, earn higher incomes, and own fewer cars than the general population (Clewlow and Mishra, 2017; Dias et al. 2017; Lavieri et al. 2017; Rayle et al. 2016; Vinayak et al. 2018). These studies also revealed that driving while intoxicated and parking are the two main issues users are trying to avoid when they decide to use ride-hailing services. Furthermore, Clewlow and Mishra (2017) found that about 9% of the individuals they surveyed claimed that the existence of ride-hailing services had lead them to dispose of one or more of their household vehicles. Curiously, this specific finding was later corroborated by Hampshire et al. (2018): they found that approximately 9% of ride-hailing users purchased an additional private vehicle after Uber and Lyft suspended their activities in Austin, TX in May 2016 (see more about this service interruption in the third section). More recent studies that focus specifically on millennials have shown that older, more educated and employed millennials tend to use ride-hailing services more frequently than other millennials (Alemi et al. 2018, 2019). In another recent study, researchers collected data on a sample of commuters in the Dallas-Fort Worth area and found that certain attitudinal factors (specifically pro-environmental, technology-embracing, and variety-seeking attitudes) contribute to increased ride-hailing use, and therefore should be considered alongside individual sociodemographics as key determinants in ride-hailing use models. They also found that the delays caused by picking up additional passengers are greater barriers to sharing rides (i.e., using the "pooled" service) than the actual presence of strangers in the vehicle (Lavieri and Bhat, 2019a, 2019b).

The studies mentioned so far used fairly traditional data collection processes. Kooti et al. (2017) employed a significantly less orthodox (yet no less effective) data collection process: the authors partnered with Yahoo to investigate the receipts sent by Uber to riders' email addresses after a trip was completed. This gave the researchers access to trip-level information from approximately 59 million rides. The authors then coupled the data mined from the receipts with Yahoo's own data, which contained users' demographics. Using this composite data set containing trip-level data as well as user demographics, the authors showed that the average active Uber rider is a female individual in her mid-20s with an above-average income. They also found that older riders tend to make longer trips and use more expensive ride-hailing services than younger riders. Unsurprisingly, they also found that users with higher income levels are more likely to use the more expensive services. In their study, Kooti et al. (2017) found that users with higher incomes are only slightly more likely to take rides during surge pricing periods, but it seems that age plays a much more significant role in this respect, making younger adults much more likely to use ride-hailing services during surge periods.

A more recent trend in the behavioral analysis of ride-hailing has been to make use of disaggregate trip-level ride-hailing data sets, such as City of Chicago (n.d.), City of New York (n.d.), DiDi (n.d.), and RideAustin (2017). Some of the studies that use these data include Dias et al. (2018), Gerte et al. (2018), Komanduri et al. (2018), Lavieri et al. (2018), and Wenzel et al. (2019). Using this disaggregate data, authors have found that ride-hailing trips are heavily concentrated on weekend evenings (Friday, Saturday, and Sunday), and that trips to and from the airport represent about 5% of all ride-hailing trips. Researchers have also found that ride-hailing trip generation has a "geographic spill-over effect" (i.e., areas with high levels of ride-hailing trip generation are likely to increase their neighbors' trip generation rates). The data have also served to show that deadheading (i.e., driving without a passenger) constitutes approximately 37% and 50% of ride-hailing drivers' miles driven and travel time, respectively. It has also been estimated that ride-hailing has had a 41%–90% net increase in energy consumption when comparing current personal travel patterns to those before ride-hailing companies were widely available. The disaggregate data have also been used to show that the unbounded growth of ride-hailing services observed on the macroscopic level is not observed on the local scale: there does seem to be a point when ride-hailing use stops growing and simply stabilizes.

Automation

It is no secret that ride-hailing companies have been interested in expanding their business models to incorporate self-driving autonomous vehicles that do not require drivers. All four of the major ride-hailing companies (Uber, Lyft, Didi, and Ola) have already announced significant investments and partnerships to reach this goal. One of their main objectives is to cut costs significantly by reducing labor wages: once drivers are no longer needed, the financial resources that once went toward paying them for their labor can be redirected to reducing customer fares, maintaining the autonomous fleet's upkeep, and potentially increasing profit margins. Another purported benefit is that autonomous vehicles have the potential of being safer than human-driven vehicles due to their decreased reaction times and their more accurate sensing capabilities.

The path to fully autonomous fleets, however, is not entirely clear since it represents a significant departure from ride-hailing companies' current business model. Presently, the individuals that drive for ride-hailing companies are (in most cases) not legally seen as the ride-hailing companies' employees—drivers are instead seen as contractors, and the vehicles they use during rides are their own private vehicles, and are not owned by the ride-hailing companies. In an autonomous future where drivers are not needed,

this model would be absolutely unsustainable. In that case, it is most likely that ride-hailing companies will have to own their autonomous fleet. Another possibility is that there will be enough people who privately own autonomous vehicles and are willing to lease these vehicles out to ride-hailing companies during the time they do not use them (which, for nonautonomous vehicles has been estimated to be around 95% of the time, according to [Shoup, 2017](#)). This would allow the vehicle owners to earn some extra cash while not having to actively perform any kind of work and, in turn, allow ride-hailing companies to reduce the size of company-owned autonomous fleets.

This shift toward automation might also represent a potential threat to the hegemony of the private vehicle's mode share seen in most US cities. The exponential growth ride-hailing services have experienced since their creation exemplifies the population's wide interest in private vehicle door-to-door transportation services. If ride-hailing companies do indeed find a way to offer an autonomous alternative that is both cheaper and offers even more privacy than current taxis and ride-hailing services (due to the absence of drivers), this might actually shift the current paradigm of privately-owned vehicles to another where most vehicles are owned by an oligopoly of ride-hailing companies and their vehicles are shared across large swaths of the population. Some authors defend that the confluence of ride-hailing services with autonomous vehicles might bring forth several other synergistic benefits, such as improvements in vehicle-miles traveled per person, vehicle occupancy levels, vehicle sizes, and commute lengths ([Greenblatt and Shaheen, 2015](#)). Further reviews of the implications of the use of autonomous vehicles can be found in [Bagloee et al. \(2016\)](#), [Chen et al. \(2016\)](#), and [Fagnant and Kockelman \(2014\)](#).

Whatever direction ride-hailing companies decide to take, it seems inevitable that autonomous vehicles are going to play a central role in their future. That being the case, transportation agencies need to consider scenarios where ride-hailing services use both human-driven and autonomous vehicles.

Conclusions

Ride-hailing services have shown to be widely successful across the globe in attracting new customers. This is likely due to a confluence of several factors, some of the most important ones being the convenience and comfort they bring and their arguably low costs to users. The introduction of this new service into the transportation landscape has brought forth both positive and negative consequences, such as providing increased accessibility to transit deficient locations, while also disrupting and upsetting the taxi market. They seem to have curtailed private vehicle travel for certain use cases (e.g., avoiding driving while intoxicated), but their impact on overall private vehicle usage remains comparatively negligible. Ride-hailing can have both complementary and substitutive effects on transit, but the dominance of one effect over the other seems to vary on a case-by-case basis. The future of ride-hailing systems is still somewhat unclear: companies seem to be strongly invested in developing self-driving autonomous vehicles, but it is currently impossible to tell if this will effectively lead to a significant shift away from private vehicle ownership and toward a true sharing economy. Academics are starting to piece together what currently drives people to use ride-hailing services and how they engage in differently priced tiers of service (such as private versus pooled), but understanding the long term effects of these services on travel demand is likely going to require much more research.

Introduction

Transportation modeling and planning software is as vast as the field of transportation planning itself. Software packages have been developed to aid practically every aspect of transportation modeling and planning:

- the application of four-step and activity-based travel demand models;
- the application of traffic microsimulation models and to aid in the timing of traffic signals;
- the estimation of demand for and benefits of transportation demand management strategies;
- the estimation of air quality impacts of planned transportation infrastructure; and
- the application of strategic planning models.

This chapter focuses on software developed specifically for application of four-step and activity-based travel models. Such software goes back to the very beginnings of transport modeling, which is described in the first section on the history of travel modeling and planning software. The chapter then describes the main features of modern transport modeling software. The chapter concludes with recent developments and future directions of modeling software.

Historical Overview

The Detroit Metropolitan Area Transportation Study (DMATS) in the early to mid-1950s is cited as the first application of a travel demand model to a regional transportation plan in the United States (Boyce and Williams, 2015). The models were implemented on the IBM 407 accounting machine, capable of simple calculations and utilizing punch cards as input and paper output. Model calculations were only partially implemented using the computer; the rest of the calculations were performed manually. The Chicago Area Transportation Study of the mid to late 1950s advanced travel forecasting practice significantly beyond DMATS by utilizing Moore's (1957) shortest route algorithm () to the Chicago area network and zone system, coupled with an incremental assignment procedure (Boyce and Williams, 2015). The models were implemented on an IBM 704 mainframe computer. A capacity constrained 24-hour one-iteration assignment with 584 zones took 7 h to complete.

In the 1960s, the Bureau of Public Roads (BPR) developed a set of procedures and "batteries" of mainframe computer programs for the implementation of travel demand models. These focused mostly on road planning but included rudimentary mode split models. These programs drew heavily from the DMATS and CATS work as well as other travel models developed for Washington DC and other regions. The US Department of Housing and Urban Development developed a suite of BPR-compatible programs specifically for transit modeling, including transit network path building, transit skimming and assignment, as well as mode split capabilities. These programs became the basis of the Urban Transportation Planning System (UTPS) software in the 1970s. UTPS consisted of 13 software modules that ran in batch mode on IBM 360/370 series of computers. It included highway and transit network analysis models, demand forecasting models, matrix manipulation, and limited graphics capabilities. These programs were refined and added to over time, forming the basis for several other mainframe-based modeling software programs.

It should be noted that during the initial development stage of these modeling tools, mainframe computers were too expensive to be owned by planning agencies. This required the agency to purchase time on mainframes owned by service bureaus, corporate computing facilities, large universities, or federal agencies. Such requirements surely limited both the complexity of early travel demand models as well as their widespread adaptation.

The availability of microcomputers starting in the late 1970s was a turning point for the availability of travel demand models and choices of travel modeling software packages. Modeling software was now being developed and sold to government agencies,

research institutions, and consulting firms by private entities. Among the packages initially developed in the 1980s for microcomputers were EMME/2, MINUTP, QRS II, SATURN, System II, TMODEL2, TRANPLAN, TransCAD, TRIPS, and VISUM/VISEM. Most of these software packages were available for IBM-PC, but some (EMME/2 and VISUM/VISEM) were programmed for the Unix operating system due to the increased computing power of Unix compared to MS-DOS at that time. Interestingly, nearly all of these packages are available today in some form. For example, INRO consultants now sell EMME; MINUTP, TRANPLAN, and TRIPS became the basis for Citilabs Cube software. SATURN is sold by Atkins, PTV sells VISUM/VISEM, and Caliper sells TransCAD. Another transportation modeling package, [Aimsun](#), grew out of work to develop a traffic microsimulation tool by faculty at the Polytechnic University of Catalonia in the 1990s, and now offers both microscopic and mesoscopic modeling capabilities similar to other packages mentioned earlier.

Transportation Modeling Software Data and Features

Many if not all transportation modeling software packages have several core features and functionalities required for modern transportation planning and modeling. Core data elements of transportation software packages are listed as follows.

Core Data Elements

- **Zones:** Travel models typically aggregate space into Transportation Analysis Zones, or TAZs. These are typically around the size of a Census Tract or a Census Block Group, though potentially smaller. Zonal data describes the quantity or quality of land-use and travel opportunities in each TAZ. TAZ data typically include households by type, employment by type, population, school enrollment, square footage of space by type, parking costs, terminal times (time required for picking up and dropping off passengers), and fields used to identify special destinations such as airports, hospitals, and major universities. Zones can also be used to group smaller sets of zones into larger areas referred to as districts.
- **Network:** A representation of the transport system. Common network elements include:
 - **Nodes:** Representation of a link end point. Typically located at road intersections, changes in road attributes (speed, number of lanes, etc.), transit stops, and to connect regular links to centroid connectors. Nodes used to be used to give “stick” networks shape, but this is typically not necessary any longer due to the use of shape points in most modern transport software packages. Common node attributes include the Node ID, XY location, an indicator identifying whether the node is a centroid, and one or more other attributes useful for modeling purposes (whether the intersection is signalized, permitted turning movements, etc.).
 - **Centroids:** A special type of node used to represent demand loading points on the network. Typically located at the center of a zone. Some software packages (e.g., Cube) require that centroid nodes be sequentially numbered from 1 to N where N is the total number of zones.
 - **Transit stops:** A special type of node used to represent a boarding and/or alighting location for transit.
 - **Links:** A representation of the road network, bike network, and/or pedestrian network. A link is defined by its endpoints, typically referred to as the “A” node and the “B” node. Link attributes include the number of the endpoint nodes, number of lanes, facility type, free-flow speed, road name, link capacity, traffic count (used for validating model outputs), and so on. Some software require a separate link for each direction of travel, whereas other software allows for special codes to identify one-way versus two-way links. Special links are also often created for transit; for example, transit-only links are used for routing grade-separate transit routes, and transfer links are used by transit path-builders to find a transfer connection between transit stop nodes.
 - **Transit routes:** Transit routes typically are specified via a route table and a route itinerary table. The route table describes the route metadata, and typically includes the route ID, route name, direction, fare, and headway for each time period. The route itinerary table describes the route alignment by listing the links and/or nodes that the route traverses from its starting point to its ending point. The route itinerary can optionally include the specific boarding and/or alighting movement allowed at each stop node, the travel time between nodes (particularly for grade-separated transit), and other relevant data.
 - **Matrices:** Two-dimensional data tables where each row and column correspond to a TAZ. Used for storing trips between TAZs output from trip distribution and mode choice models, as well as travel time, distance, and cost between zones output from path-building procedures. The latter are commonly referred to as network “skims.” Trip tables are often segmented by some combination of socioeconomic market segment, trip purpose, mode, and/or time period. It should be noted that trip tables from four-step travel models could be represented in “production-attraction format”¹ or “origin-destination format,” depending upon the

¹ The production end of a trip is the home end of home-based trips and the origin of a non-home-based trip. The attraction end of a trip is the non-home end of a home-based trip and the destination of a non-home-based trip. A production-attraction format trip table is one in which rows are production zones and columns are attraction zones.

type of model or process that created it. Skims are often segmented by time of day. Transit skims typically separate in-vehicle time from out-vehicle time, and include number of boardings or transfers as additional attributes.

- Volume-delay functions: Volume-delay functions are used to reflect the effects of congestion on travel time. One of the first and perhaps still the most common volume-delay function (VDF) was published by the BPR ([Bureau of Public Roads, 1964](#)). Most modern software allows the user to specify any type of VDF, of which there are many.
- Turning movement prohibitors: Specifies disallowed turning movements, or travel time penalties for specific movements. Typically specified by from node, through node, and to node.

Core Software Features

The following section lists main features and capabilities of modeling software.

- Data input/output: Most software has capabilities to import and export networks from shapefile format, comma-separated value (CSV) format, database format (DBF), Excel (XLSX) Open Street Map (OSM), General Transit Feed Specification, and/or other transportation software programs. Tabular and matrix data can often be imported and exported from/to CSV, DBF, XLSX, and other formats. Background layers (OSM, Google Maps, satellite images) can be loaded from the web or disk.
- Network editing: A graphical tool for displaying and editing network features. This tool is used for adding and removing links, nodes, and transit routes, adding to or changing the attributes of links, nodes or routes, etc.
- Network calculations: A tool for calculating network attributes, such as link capacity, from other attributes, such as number of lanes and other attributes. Network calculations are often used to automate modeling procedures, such that the user can rely on programmed calculations rather than manually change multiple data items.
- Matrix calculations: A tool for creating and calculating matrix data. For example, performing mathematical operations on matrices (adding, subtracting, multiplying matrices), and transposing matrices². Matrix calculations can be used to apply travel demand models, such as gravity models and logit mode choice models. Iterative proportional fitting (IPF), known as Fratar adjustment for two-dimensional matrices, is a special type of matrix calculation required for doubly constraining gravity models but has other applications in travel demand modeling as well.
- Traffic path building and assignment: Tools for finding paths between nodes and/or TAZs through road, bike, or pedestrian networks, and assigning demand to those networks. Inputs include networks, demand matrices, and volume-delay functions. Outputs may include congested travel times on links, network skims, and link volumes.
- Transit assignment: Tools for finding paths between nodes and/or TAZs through transit networks, and assigning demand to those networks. Inputs include road and transit networks, transit demand matrices, and transit delay functions. Outputs may include transit skims, route level and stop level boardings and alightings, and transfer matrices.
- Select link/route tracing: The analyst may be interested in identifying the demand associated with one or more selected links or transit routes. Or they may be interested in tracing the routes used by one or more zone pairs through the assignment process. Such analysis is typically required in the case of traffic impact studies or project-specific analysis. In either case, most software packages provide this capability.
- Visualizing and reporting results: Travel demand models are a tool that, if successful, provides useful insights into the alternatives and policies being modeled. To that end, the visualization and reporting of results is a valuable feature of modern transportation modeling software packages. Following are a few common types of reports and graphics available from most modeling software packages:
 - Link bandwidth plots: Plots in which the thickness of the link is displayed according to the link flow, and the color of the link is displayed according to the volume to capacity ratio on the link. This plot is useful for understanding roads with high demand and/or congestion.
 - Route passengers and boardings: Plots of the transit network where each route segment is scaled to passenger flow. Transit stops can also be scaled or colored by boardings/or alightings.
 - Thematic maps: Typically used to display zonal or other network data not mentioned earlier (i.e., household density, trips by zone, link capacity, etc.)
 - Trip length frequency distributions: A matrix histogram or bar chart, in which the x-axis is trip distance and the y-axis is the absolute number or percent of trips in each distance bin. These plots are useful for understanding how far people are traveling, often by trip purpose.
 - Desire lines: A visualization of a matrix showing flows between zones or districts as lines whose width is scaled to demand.
 - Other statistics and reports: Vehicle miles of travel, vehicle hours of travel, transit boardings by route, trips by mode, trips by distance, and many other statistics are useful outputs from travel demand models and are commonly available from transport modeling software.
- Automation: Travel models can take hours if not days to run from start to finish. Therefore automation is a required core feature to ensure replicability, accuracy, and efficiency and reduce labor costs and fatigue. Various software packages have implemented

² A transpose matrix is one in which the rows and columns of the original matrix are flipped. A common application of matrix transposition is when changing a matrix format from production-attraction to origin-destination format.

automation in different ways. For example, both Cube and TransCAD have developed their own scripting languages, though TransCAD also provides an application programming interface (API) that can be called from other modern programming languages. EMME and VISUM/VISEM rely upon Python as the main scripting language, and provide an API for software data program functionality. The model developer and/or user must implement each model component either in the modeling software scripting language or in the API language when developing or enhancing the model. The model developer must ensure that the model steps can run for different scenarios and provide outputs that provide useful insights for decision-making.

Additional Features

Over time, as software has evolved and user needs have become more complex, software developers have added a number of additional features to enhance the usability of their software. A few examples are provided as follows.

Geographic Information System (GIS) integration: Modern transportation modeling software allows the user to perform common GIS functionality: intersect, union, buffer, tag to nearest, etc. across various point, line, and polygon layers. This functionality is either provided as a core feature of the software or through an add-on such as an ESRI ArcMap license.

Scenario management: Analysts often code dozens or even hundreds of scenarios when working on a metropolitan transportation plan or project analysis. Scenario management tools have been developed to organize different versions of networks and inputs for each scenario. The user often has the ability to select various bundles of projects to include in a specific scenario, limiting the amount of recoding required to apply the same project across multiple scenarios.

Subarea extraction: Often planners working in larger metropolitan regions need to carve out a subarea from the regional model, adding network and zonal detail to that smaller area for a specific planning study such as a road project, traffic impact study, or community plan. To enable this procedure, software vendors often provide a subarea procedure where the analyst identifies the boundaries of the area of interest and the zones to be included in the subarea, and the software extracts a subarea network from the regional network along with demand associated with that subarea. The software may additionally allow disaggregation from more aggregate to more disaggregate TAZ systems within the subarea as well as aggregation of demand at external stations outside the subarea, based on the regional assignment.

Origin-destination matrix estimation (ODME): ODME is a process whereby a base demand matrix is adjusted to match traffic counts through an iterative process consisting of highway assignment, comparison to counts, and matrix algebra to improve goodness-of-fit. Although there is considerable debate about the usefulness and validity of such automated adjustments, ODME functionality has been added to most software packages to provide this option to those who want it.

Expansion of choice models and algorithms: Software vendors are constantly moving research into practice in order to maintain their competitive edge and provide their users increased capabilities and faster runtimes. Software packages now support a multitude of highway assignment techniques: Frank-Wolfe static equilibrium, stochastic, origin-based assignment, etc. Transit assignment methods have also increased to include shortest path, stochastic, and frequency-based assignments. Some software packages have added automated tools for applying multinomial and nested logit choice models.

Support for disaggregate models: Due to the increasing adoption of activity-based models, software vendors have added support for various aspects of disaggregate travel models, such as record-based processing, expanding their data models to consider household and person data, simulating from probabilities, and so on. Despite these features, most activity-based models continue to be implemented in stand-alone software.

Cloud computing: In order to reduce runtime and agency IT costs for large-scale travel models, many software packages are offering either cloud computing services through the company or network licenses, which allow the software to be deployed in the cloud. Typically additional configuration is required to support distributed computing and not all algorithms are distributable at this time.

Activity-Based Models and the Open-Source Revolution

As discussed earlier, many of the software packages in use today have their roots in the four-step models of the 1970s and 1980s. Starting in the 1990s, activity-based models began to emerge as a practical alternative to the four-step approach. Their adoption was motivated by a desire to model behaviors and policies that are not addressed by the majority of trip-based models; trip-linking, activity (re)scheduling in response to congestion, travel demand management, certain pricing policies, and so on. As these models required model forms and application procedures that did not exist or at best were very cumbersome to implement in most transport modeling packages (list-based processing, simulation from probabilities, choice models with thousands of alternatives, etc.), activity-based modelers developed their own software to implement their models. In such cases the software became intrinsically tied to the specific model implementation—unlike commercial transport software in which any given package can be used in dozens or hundreds of different regions with significantly different model features. Some of the more commonly applied activity-based models for planning agencies in the United States are DaySim, CT-RAMP, and TourCast. Each software package relies on one of the commercial transport modeling packages for network and matrix calculations, such as network skimming and assignment, as well as application of aggregate models for commercial vehicles and/or other special markets (Davidson et al., 2007).

We are now seeing an increasing interest in the development of open-source tools in the transport modeling industry. Two popular software packages for data science and statistics—Python and R—are increasingly being applied to analyze transport data

and implement travel demand models. Both software tools are firmly rooted in the open source paradigm, with large user communities who develop and share libraries for specific applications that can be downloaded and applied by other developers. The ActivitySim project is an example of how the open-source philosophy is gaining traction in the modeling community. The mission of the ActivitySim project is to create and maintain advanced, open-source, activity-based travel behavior modeling software based on best software development practices for distribution at no charge to the public. The ActivitySim project is led by a consortium of metropolitan planning organizations and other transportation planning agencies, as opposed to a commercial entity (Association of Metropolitan Planning Organizations Research Foundation, 2019). MatSim, an open-source framework for implementing large-scale agent-based transport simulations is another example (Horni et al., 2016).

Future Directions for Transportation Planning and Modeling Software

Travel modeling software vendors face significant challenges due to the evolving demands of transportation planners and decision-makers. Increasingly the focus of transportation planning is turning from analysis of additional capacity to management, maintenance, and reliability of the existing system. The emergence of Mobility-as-a-Service, the increasing use of transportation network companies as an alternative to the use of the privately owned automobile, the substitution of internet shopping and home delivery for shopping travel, and the potential availability of autonomous vehicles poses additional questions about equity, congestion, and quality of life. Travel modelers increasingly recognize that four-step travel models coupled with static equilibrium assignments are incapable of accurately measuring congestion due to increasing demand, system reliability, fleet management, and how emerging technologies could potentially revolutionize how, when, and how much people travel. To address these needs, software vendors are increasingly investing in new methods to model travel. Such features include integration of dynamic traffic assignment software and/or traffic microsimulation software and vehicle routing models within their modeling platforms. It remains to be seen, however, whether the traditional transportation modeling software with roots in the planning processes of the 50s and 60s can evolve to keep up with the planning questions of tomorrow.

Introduction

Transportation modeling as a science, or a profession is entangled with statistical methods being used to discover patterns in the data provided by users of the transportation system or the system itself. Transportation data and models are used to develop understanding about the performance of the system when characteristics of the system and users are changed, mainly for forecasting purposes. Therefore, enhancing the quality of data and modeling techniques which are used for development of transportation models, that can then assess the potential effectiveness of policies for forecasting, is essential for planning purposes. This significance gets further amplified when we know that the transportation network is the most expensive infrastructure that is still being managed by the public sector. Therefore, it is crucial to identify, and measure the value of the most beneficial strategies for improving the level of service and experience on the transportation network as well as their impacts on the well being of users and nonusers. Evolving and constantly advancing statistical methods and data sources are the backbone of the process of development of transportation models for forecasting transportation related indicators such as travel time, reliability of network, traveling cost, and number of users on the network. In this article the most fundamental approaches used in different discipline of the large field of transportation modeling and engineering are discussed. The first section of the article provides a list of major tests, concepts, models, and techniques, which are commonly used by transportation modelers as well as some discussion on the surveying methods to be used for collecting these data sources. The second section discusses the types of databases that are used.

Statistical Methods

Akaike's Information Criterion

As an information criterion and a goodness-of-fit estimator, AIC measures the quality of a statistical model based on the best (maximum) log-likelihood value that can be obtained given a specific number of parameters. Therefore, AIC falls into the set of estimators that are adjusted based on the number of parameters to avoid overfitting. The main use of AIC is for model selection for a given data, where lower values of AIC are considered better, however, AIC is silent about how better a model with lower AIC is. For a given model, with p parameters and log-likelihood value of $LL(\beta)$ for β as the vector of parameters of size p , $AIC = -2[LL(\beta) - p]$.

Analysis of Variance (ANOVA)

The analysis of variance is closely related to linear regression analysis. So, first we consider a simple linear regression model as below, and then discuss ANOVA from the linear regression point of view.

$Y_i = \alpha + \beta X_i + \varepsilon_i$, where Y_i is the dependent variable, α is the constant or intercept of the linear function, β is a $[1 \times p]$ vector of parameters for X_i , which is a $[p \times 1]$ vector of explanatory variables and ε_i is the unobserved residual for individual i . α and β can be estimated using methods such as ordinary least square.

One property of the linear regression model is that the line passes through the sample means of $\bar{Y}$ and $\bar{X}$. In other words, $\bar{Y} = \alpha + \beta \bar{X}$. Therefore, we can subtract both sides of the main regression equation from the sample mean equation to have $Y_i - \bar{Y} = \beta(X_i - \bar{X}) + \varepsilon_i$. By defining new variables that are based on the deviation from the mean, we have $y_i = \beta x_i + \varepsilon_i$, where $y_i = Y_i - \bar{Y}$ and $x_i = X_i - \bar{X}$. Then by squaring both sides of the regression function for deviation from the mean model and summing over the sample data we have:

$$\sum_i y_i^2 = \beta^2 \sum_i x_i^2 + \sum_i \varepsilon_i^2 + 2 \sum_i \beta x_i \times \varepsilon_i.$$

Then we can say $\sum_i y_i^2 = \beta^2 \sum_i x_i^2 + \sum_i \varepsilon_i^2$ because $\sum_i \beta x_i \times \varepsilon_i = 0$. Now we define $\sum_i y_i^2 = \sum_i (Y_i - \bar{Y})^2$ as the total sum of squares (TSS), $\beta^2 \sum_i x_i^2$ as the explained sum of squares (ESS), and $\sum_i \varepsilon_i^2$ as the residual sum of squares (RSS). This means TSS to be equal to RSS + ESS. The study of these three terms is called ANOVA. Assuming a sample of size n , TSS has a degree of freedom of $n - 1$ because it reflects the deviation of the sample data from its mean. RSS has $n - p - 1$ degrees of freedom where p is the size of the vector of parameters that are estimated. ESS has p degrees of freedom, which is the number of parameters estimated. By dividing these three terms by their degrees of freedom, we obtain the mean sum of squares, which can then help us define the F variable, which follows an F-distribution.

$$F = \frac{MSS \text{ of ESS}}{MSS \text{ of RSS}} = \frac{\beta^2 \sum_i x_i^2 / p}{\sum_i \varepsilon_i^2 / (n - p - 1)} = \frac{\beta^2 \sum_i x_i^2 / p}{\sigma^2},$$

where σ^2 is the variance of the error term. The F ratio can be used to test the hypothesis that β is meaningfully contributing to explain the dependent variable. The well-known ANOVA table is commonly generated by commercial statistical packages (Gujarati, 2009)

ANOVA Table

Source of variation	Sum of square	df	Mean sum of squares
ESS	$\beta^2 \sum_i x_i^2$	p	$\beta^2 \sum_i x_i^2 / p$
RSS	$\sum_i e_i^2$	$n - p - 1$	$\sum_i e_i^2 / n - p - 1$
TSS	$\sum_i y_i^2$	$n - 1$	

$$F = \frac{\beta^2 \sum_i x_i^2 / p}{\sum_i e_i^2 / n - p - 1}$$

Anderson–Darling Tests

Anderson–Darling (AD) test belongs to the category of distance-based tests for examining the similarity of two distributions or a sample belonging to a distribution.

If X is a random variable or $(x_1, \dots, x_n)$ with cumulative density function of $F_s(X)$ which it is tested against another distribution $F_b(X)$, then the distance between the two distributions can be estimated using the following statistic:

$$D_w^2 = n \int_{-\infty}^{\infty} [F_s(x) - F_b(x)] w[F_b(x)] dF_b(x),$$

where $w[F_b(x)]$ is a positive weight function.

The AD statistic considers $w[F_b(x)]$ to be equal to $1/[F_b(x)[1 - F_b(x)]]$. Further, $F_b(x)$ and $F_s(x)$ should be transformed to uniform distributions to form a simple formulation for the AD statistic when a sample is being tested for a specific distribution. By defining a new random variable $U = F_b(x)$ with $\Pr\{U \leq u\} = u, 0 \leq u \leq 1$ and defining an empirical distribution function for the sample $(x_1, \dots, x_n)$ as $F_s(x) = k/n$ for k from $(x_1, \dots, x_n)$ and the sample being ordered then it can be shown (Anderson and Darling, 1954) that the AD statistic can be estimated by:

$$D_{AD}^2 = -n - \sum_{k=1}^n \frac{2k-1}{n} \{\log[F_b(x_k)] + \log[1 - F_b(x_{n+1-k})]\}.$$

They also showed that the critical value for 5% significance is 2.492 and for 1% is 3.880.

Autocorrelation in Regression

When there is correlation between ordered observations in time or space resulting in the covariance between the error terms being nonzero, autocorrelation occurs. In the context of OLS, where the dependent variable (even if it is observed for multiple times) is regressed only against the explanatory variables (and not the dependent variable observed for the previous time intervals), the estimated parameters remain unbiased (their expected value is equal to the true values), and asymptotically normally distributed. However, the coefficients are not any more efficient (not having the minimum variance) which means the t and F statistics are not any more reliable.

$Y_t = \alpha + \beta X_t + \varepsilon_t$, which can be simply written as $Y_{t-1} = \alpha + \beta X_{t-1} + \varepsilon_{t-1}$ for one time interval earlier than t and can be written for s time intervals earlier as $Y_{t-s} = \alpha + \beta X_{t-s} + \varepsilon_{t-s}$. To examine the first order autocorrelation, $\varepsilon_t = \rho \varepsilon_{t-1} + \varepsilon_t$, ρ can be estimated which is the main factor for examining the strength of autocorrelation as well as correcting the estimated coefficients.

There are some applications of spatial autocorrelation in the area of transport on traffic flow and origin-destination models (Bolduc et al., 1989). In the context of discrete choice modeling, there has been studies trying to capture the spatial autocorrelation into the structure of the utility function (Bhat and Guo, 2004; Bolduc, 1992), either as a systematic component or into the random error component. However, these works do not much discuss the properties of the estimated coefficients such as unbiasedness and efficiency.

When the dependent variable is present on the right-hand side of the equation, a typical time series model is of interest. The commonly known equation for times series can be written as $Y_t = \alpha Y_{t-1} + \varepsilon_t$, which can get complicated by adding a drift (a fixed value) or trend (time as t) to the right hand side. Time series models are implicitly assumed to be developed on the underlying stationary (loosely saying when the mean and variance of the data are fixed over time) data. Then by using autoregressive regression and a moving average (MA) mechanism, unbiased parameters can be estimated. If the data are not stationary, there are ways to transform it to stationary data such as by differencing i times which is denoted in the literature as $I(i)$ which is called integrated of order i .

Bayesian Nonparametric Statistics

Conditional probability of an event given occurrence of another event can be explained by the Bayes' Theorem as: $P\{A|B\} = P\{AB\}/P\{B\}$. This rule is applicable on occurrence of B given A , which then results in $P\{A|B\} = P\{B|A\}P\{A\}/P\{B\}$. As the probability of B can be written as the probability of the product of B and disjoint events whose union cover the whole space, then the previous conditional probability can be reexpressed as $P\{A_k|B\} = P\{B|A_k\}P\{A_k\}/\sum_{j=1}^N P\{B|A_j\}P\{A_j\}$ where $B = \cup_{j=1}^N A_j B$,

$\cup_{j=1}^N A_j = \text{Space}$, and $A_j \forall j = 1, \dots, N$ are disjoint. The last form of Bayes' theorem is the core of Bayesian methods with growing applications in the field of transportation.

Statistical models with infinite number of parameters in their model, which are developed based on Bayesian methods, are called Bayesian nonparametric statistics. Following the Bayesian analysis of statistical models, the parameter space Θ , which reflects the analyst's knowledge, is captured through $\pi(\theta)$. Given available data, shown as Y for the dependent variable and X for the explanatory variables, θ is aimed to be estimated. Y being a random variable is expected to be generated using a random mechanism explained through the posterior distribution. The posterior distribution is conditional on Y and provides updated information for θ as $\pi(\theta|Y)$. In the Bayesian nonparametric context, prior, and posterior distributions are defined in an infinite dimensional parameter space.

A Dirichlet process is parameterized using the concentration parameter α , which is a positive, real-valued to control the variance of the process and the base probability distribution G_0 on Θ . As α approaches zero, the process concentrates around the mean. An important property of the Dirichlet process is that if G denotes a sample generated from a Dirichlet process, $G \sim DP(\alpha, G_0)$, for any finite, mutually exclusive partition $A_1, \dots, A_k$ of the parameter space Θ , exhibits a Dirichlet distribution as $G(A_1), \dots, G(A_k) \sim \text{Dirichlet}(\alpha G_0(A_1), \dots, \alpha G_0(A_k))$, where $G(A_1)$ is the probability mass in partition A_1 . Two main properties of the Dirichlet process for any realizations of it are being discrete and clustered with non-zero probabilities. The formal definition of the Dirichlet process is not applicable to practical applications, which results in three alternative representations of the Dirichlet process have been proposed in the literature as the Blackwell–MacQueen urn scheme, the Chinese Restaurant process and the stick-breaking process construction. For more information on these processes and application of the stick breaking process in the context of shared automated vehicle service choice Krueger et al. (2019) can be consulted.

Bayesian P Values

Borrowing the P values concept from the classical frequentist domain can help Bayesians to assess the goodness of fit of a single model using the previous notation for the prior as $\pi(\theta)$, Θ as the parameter space, $\pi(\theta|Y)$ as the posterior and $g(Y)$ as the goodness-of-fit measure for the data and model $m(Y|\theta)$.

If we define the prior predictive density as $\tilde{p}(Y|y) = \int_{\Theta} m(Y|\theta)\pi(\theta|Y)d\theta$ then the posterior predictive P value can be defined as $p^* = \int_{g(Y) > g(y)} \tilde{p}(Y|y)dy$. As the observed data are used twice in the estimation of p^* , a corrected posterior predictive P value can be estimated using the method discussed by Bayarri and Berger (1999).

Best Unbiased Estimation

An *unbiased* estimator, for example parameters of a linear regression model, is an estimator whose expected value is equal to the true value of that estimator, like mean of a sample. Among all unbiased estimator the one(s) with the minimum variance is called an *efficient* estimator. Also an efficient unbiased estimator is called a *best* estimator.

Binomial Distribution

As one of the popular distributions, binomial distribution explains the chance of s successes in n independent trials where the chance of success is p and the chance of failure is therefore $q = 1 - p$. Then as random variable X , which is a nonnegative integer, is said to follow a binomial distribution $X \sim B(n, p)$ with probability mass function of

$$f(x) = P(X = x) = \binom{n}{x} p^x q^{n-x}, \text{ where } \binom{n}{x} = n! / (x!(n-x)!) \text{ for } 0 \leq x \leq n.$$

Then the cumulative density function of binomial distribution would be $F(x) = P(X \leq x) = \sum_{i=0}^x \binom{n}{i} p^i q^{n-i}$.

The Poisson distribution is derived from the negative binomial distribution for events with low chance of success with so many instances, which is discussed in detail in the Poisson distribution section. Poisson distribution and its generalization of negative binomial are commonly used in modeling count data such as accident and safety analysis.

Bivariate Distributions

Having two random variables correlating with one another requires a joint/bivariate distribution to explain the interaction/dependency between the two variables. The concepts are quite similar but we first start by discussing two continuous random variables where the duplet (X, Y) shows two random variables with a joint probability density function (PDF) of $f(X, Y) > 0$. The joint cumulative density function can be estimated by $F(X, Y) = P(X \leq x, Y \leq y) = \int_{-\infty}^x \int_{-\infty}^y f(z, w) dz dw$. The marginal pdf with regard to X can be written as $f_x(x) = \int_{-\infty}^{\infty} f(x, w) dw$, and the conditional probability of X given $Y = y$ can be written as $f(x|y) = f(x, y)/f(y)$. In a similar fashion, the probability mass function of X and Y as discrete random variables can be written as $f(x, y) = f(X = x, Y = y)$ and the cumulative mass function as $(X, Y) = P(X \leq x, Y \leq y) = \sum_{-\infty}^x \sum_{-\infty}^y f(z, w)$.

The most commonly used bivariate distribution is normal, which has the following function for the standardized normal function: $f(x, y) = \frac{1}{(2\pi\sqrt{1-\rho^2})} \exp\{-(x^2 - 2\rho xy + y^2)/[1(1-\rho^2)]\}$. In case the joint function does not have a closed form, it can be approximated using copulas, which will be explained later.

Bootstrap Methods

The bootstrap method is a statistical technique to indirectly infer properties of a population by forming small random samples. The random samples are constructed by drawing observations from a large data sample, or some prior information about the distribution of the population, one at a time and returning them to the data sample. This process is called sampling with replacement, which then allows one observation to appear in the sample multiple times. Therefore, the resampled sets are used to infer true properties of the population.

Chi-square Distribution

Chi-square distribution is one of the most popular distributions used in statistics and consequently transportation modeling. It is closely related to the normal distribution and formed as sum of squares of j independent standardized normal variables, which is called as the χ^2 distribution with k degrees of freedom (df). The PDF of χ^2 distribution is:

$$f(x) = \begin{cases} 0 & \text{if } x \leq 0 \\ \frac{1}{\Gamma(\frac{n}{2})} \frac{1}{2^{\frac{n}{2}}} \frac{1}{x^{\frac{n}{2}}} e^{-\frac{x}{2}} & \text{if } x > 0 \end{cases},$$

where Γ refers to the Gamma function.

For example, when estimating the variance of a random sample of n independent and identically distributed random variables shown as $\{X_1, \dots, X_n\}$, the variance of the sample can be estimated as $S^2 = \left(\sum_{i=1}^n (X_i - \bar{X})^2\right)/(n-1)$, which has a χ^2 distribution with $n-1$ degrees of freedom.

Confidence Interval

A $100 \times (1-\alpha)$ percent confidence interval is an interval around a sample parameter θ that with $\hat{\theta}$ as the true parameter of the population. It is expected that if repeated random samples of size N are drawn, $100 \times (1-\alpha)$ percent of the time, the interval around θ includes $\hat{\theta}$. This interval is a random variable of type *range*, which may or may not include the true parameter. The interval is determined by the sampling distribution, which is used to specify the probability of observing each value in the sample.

Therefore, for a given sample size N and α , the confidence interval determines the accuracy of the estimated statistic/parameter θ . The statistics determines what method to be used for constructing the confidence regions.

Copulas

Hoefding (1940) introduced the best possible boundaries for such functions as one of the earliest attempts of introducing copulas. However, the term of copula was first used by Sklar (1959). Sklar's work was followed by several others, which led to pervasive usages of copula functions in different fields such as economics (Smith, 2003), finance (Embrechts et al. 2002), medical sciences (Clayton, 1978), statistics (Frees and Valdez, 1998), and more recently transport modeling (Bhat and Eluru, 2009).

The popularity of copula functions owes to four attributes. First, although the normal distribution is the backbone of constructing multivariate distributions, the copula formulations allow for a diversity of other types of functions to capture multivariate distributions among which Gaussian distribution is one. Second, copula distributions allow for linear and nonlinear dependencies, providing both symmetric and asymptotic options. Third, the simple closed form copula functions significantly facilitate their usage in complex contexts. Fourth, various correlation structures can be handled with copula functions (Bhat and Eluru, 2009; Trivedi and Zimmer, 2007). Several copulas have been introduced among which Gaussian, Farlie-Gumbel-Morgenstern, and Archimedean class of copulas such as Frank, Joe, Gumbel, and Clayton are the most popular ones (Bhat and Eluru, 2009). For detailed information and introduction to copulas refer to the work by Bhat and Eluru (2009). More advanced copula functions such as Vine copulas (Joe et al., 2010) and nested copulas (Hossein and Mohammadian, 2016) are becoming interesting in different fields.

Degrees of Freedom

Generally speaking, the concept of degrees of freedom is referred to as the number of times that a statistic can freely vary. Therefore, every required parameter or necessary relations estimated using data for that statistic, reduces the degree of freedom of the random variable by one degree.

Dummy Variables

A dummy variable is a binary variable that can take values of either 0 or 1. Dummy variables are commonly used in regression models to transform categorical variables to numerical values. Dummy variables, especially when interacted with other variables, allow capturing seasonality in the data, taste variation, and sudden shifts in the constant parameter.

Durbin–Watson Test

The Durbin–Watson test is one of the most well-known tests to examine autocorrelation in linear regression. This test can be used to test first-order autoregression $\varepsilon_t = \rho\varepsilon_{t-1} + \varepsilon_t$, where ε_t is the error term of the regression model $Y_t = \alpha + \beta X_t + \varepsilon_t$. To test the hypothesis that $\rho = 0$ or not, given $d = \left(\sum_{t=2}^n (\varepsilon_t - \varepsilon_{t-1})^2 \right) / \left(\sum_{t=1}^n \varepsilon_t^2 \right)$ being the DW statistic, two critical values for a specific confidence interval are required. Assuming that for significance level of $(1-\alpha\%)$, critical values of dw_l and dw_u are provided, statistically significance positive autocorrelation exists if $0 < d < dw_l$ and statistically significance negative autocorrelation exists if $4 > d > dw_u$. We cannot reject the hypothesis of no autocorrelation if $4 - dw_u > d > dw_l$. For other values of d the test is indecisive which is the main drawback of the test.

Entropy

Considering a set of mutually exclusive and exhaustive of random events $\{E_1, \dots, E_N\}$ where each of the j event can be associated with a random variable x_j , the classical definition of entropy can be written as $-\sum_{i=1}^N p_i \log p_i$ where p_i is the probability of event j which can be associated with random variable X_j such that $\sum_{i=1}^N p_i = 1$. If x is a continuous random variable, entropy is defined as $\int_x P(x) \log P(x) dx$. In general entropy reaches its maximum when all probabilities are equally likely. Different usages for entropy have been discussed in the field of transportation such as in land use (Kockelman, 1997) and choice modeling Swait and Adamowicz (2001).

Expected Value

Expected value of a discrete/continuous random variable is defined as the sum/integral of that variable over all possible values of the variable weighted by their probability of happening. Therefore, it can be estimated as follows for discrete and continuous random variables.

$$\text{Discrete for } N \text{ observations : } \sum_{i=1}^N p_i x_i$$

$$\text{Continuous over } x : x \int_{-\infty}^{\infty} x f(x) dx$$

Extreme Value Distributions

Similar to the central limit theorem that talks about one property of a sample with a finite variance, the extreme value distributions are relevant to a sample with a converging normalized maximum. For a sample with a converging normalized maximum (as the sample size goes to infinity), the normalized maximum (which is a random variable) has a PDF, which belongs to either the Gumbel (Type I), the Fréchet (Type II) or the Weibull (Type III) family. These three distributions are grouped together into the generalized extreme value distribution family. Gumbel and Weibull family distributions are commonly used in the field of transportation in discrete choice modeling (Train, 2009) and hazard-based analysis (Ghasri et al., 2018).

F Distribution

F Distribution is closely related to normal and chi-square distributions. In simple words, let X_1 and X_2 be two independent random variables with chi-square distributions. Define a new random variable based on the ratio $F = (X_1/df_1)/(X_2/df_2)$, where df_1 and df_2 are degrees of freedom of X_1 and X_2 , respectively. Then F follows an F distribution with df_1 and df_2 degrees of freedom. F distribution is commonly used in ANOVA analysis and linear regression modeling. The PDF of the F distribution is not directly used while the corresponding cumulative density function tables are readily available in statistics textbooks.

Factor Analysis and Principal Component Analysis

Factor analysis (Explanatory Factor Analysis, EFA) is a type of latent variable modeling, which is developed by using observed/measured variables (x_i). A linear relationship between the latent variable/factors are considered in the EFA where an unobserved error term is also present. Therefore, latent variables and their weights (their contributions in explaining the observed values in the measurement equations) are estimated in the factor analysis, in a way that $x_i = \alpha_0 + \beta f + \varepsilon_i$ in which β is the vector of coefficients/

weights (of size p) to be estimated and f is the vector of factors (of size s). The number and value of the factors is unknown. The error term ε_i follows a normal distribution with mean zero and variance σ_i . There is a possibility to consider relationships between the factors in latent variable modeling, which is not common in EFA.

In case the purpose of the analysis is to reduce the dimension of the data (x_i) and there is an assumption that there is no unobserved error term, the principal component analysis (PCA) is used. In PCA $x_i = \beta s$, score (s) are and weights β are estimated based on minimizing the sum of squared perpendicular distance to the component axis such that the correlation between the scores are minimized.

Examples of using EFA and PCA in transport modeling can be found on topics such as travel attributes (Rashidi and Mohammadian, 2011a, 2011b), emission, (Rashidi et al., 2015), and land use (Kockelman, 1997).

Hypothesis Testing

Model estimation and hypothesis testings are always discussed together, because parameters estimated using a sample are not necessarily close enough to the true parameters estimated based on the population. Therefore, a hypothesis is developed to examine whether the estimated parameters are sufficiently close to true parameters based on statistical measurements, knowing that all is available in the sample. Typically, the *null hypothesis* is formed around the hypothesis that the estimated parameter is equal (close) to the true parameter and the *alternative hypothesis* negates this hypothesis.

To test the null hypothesis, the sample is used to calculate a *test statistic*, which is associated with a probability which is then used to use the *confidence interval* or *test of significance*.

Assuming X as a random variable based on a sample, and parameter μ measuring some information about X , for example mean of X , μ becomes a random number with a specific PDF. Then for any confidence level (α), using the PDF of μ , a range for μ can be obtained such that $\mu_l \leq \mu \leq \mu_u$ (this is called acceptance region, with μ_l, μ_u being the critical values). This means for a null hypothesis, for example, $\mu = \tilde{\mu}$, if $[\mu_l, \mu_u]$ does not include $\tilde{\mu}$ then the null hypothesis can be rejected, otherwise, the null hypothesis cannot be rejected (note that it is not accepted, it is just not rejected).

Gamma Distribution

Gamma distribution is commonly used in the field of transportation for estimation of heterogeneity (Lord, 2006; Rashidi and Mohammadian, 2011b), trip distribution (McNally, 2000), trip generation (Wilmot and Stopher, 2001), and travel time variability (Susilawati et al., 2013).

Gamma distribution with three parameters for a random variable X can be written as:

$$\Pr(X = x, l, s, \gamma) = \frac{1}{s\Gamma(\gamma)} \left(\frac{x-l}{s} \right)^{\gamma-1} \exp\left(-\frac{x-l}{s}\right), l < x < \infty, s > 0, \gamma > 0,$$

where s is the scale parameter, l is the location parameter and γ is the shape parameter. In this notation, mean is equal to $s + \gamma + l$ and variance is $s^2 \times \gamma$, exponential distribution is a special case of gamma distribution where the scale parameter is one and location is zero.

Geometric and Negative Binomial Distributions

The negative binomial distribution is commonly used in accident analysis (Washington et al., 2010). This distribution is used to measure in a discrete probability of the number of successes in a sequence of iid Bernoulli trials (only two outcomes are viable, success and failure) before a specified and nonrandom number of successes occurs. If the number of success is 1, the distribution is called geometric design.

If the probability of success is p and the probability of failure is $q = 1 - p$, the probability of s successes and f failures for a random variable X :

$$\Pr(X = s) = \binom{f+s-1}{s} p^s q^f, \text{ where } \binom{f+s-1}{s} = \frac{f+s-1}{s!(f-1)!}.$$

The expected number of trials before observing s successes (or f failures) is

Heteroscedasticity

Heteroscedasticity (or heteroskedasticity) is used when the variance of a random variable (dependent variable) changes across another variable that is used to predict (explanatory variable or independent variable) it. Its opposite is called homoscedasticity, which can be written in mathematical format as: $\text{var}(Y|X) = \sigma^2$ which is fixed and not varying across different values of X s.

In linear regression, where ordinary least square is used, at presence of heteroscedasticity, the estimations are not anymore BLUE. BLUE estimations can be obtained when instead of OLS, the weighted least squares method is used, provided the fact that σ_i^2 are known. In this method, the dependent variable, the independent variables, and the residuals are weighted by the known σ_i .

To detect presence of heteroscedasticity, White's general heteroscedasticity test is the most well-known approach where the square of residuals are regressed against the explanatory variables, interactions of explanatory variables and/or higher powers of

them. When σ_i s are not known, White's heteroscedasticity-corrected standard errors are estimated where squared residuals are used in place of $\text{var}(Y|X) = \sigma^2$ in estimation of the variance of the coefficients.

Identifiability

A parameter of a model for a random variable, say Y is identifiable if for two different values of the parameter, different probability values are obtained.

In practice, for a given sample drawn for the random variable, a unique value can be estimated for the parameter. If this is the case, then the parameter is called identifiable. Identifiability can be empirical or theoretical. For example, [Bhat and Eluru \(2010\)](#) state that there are empirical identification issues for jointly estimating satiation parameters in the MDCEV formulation. In the random utility maximization formulations, it is quite well known that only the difference between utilities matters. This results in a theoretical identification issue for estimation of alternative specific parameters for all alternatives ([Train, 2009](#)). More details on identification issues of the logit kernel models is available in the paper by [Ben-Akiva et al. \(2001\)](#).

Kolmogorov–Smirnov Test

KS test is a nonparameter test to examine the similarity of two probability distributions, an empirical sample and a probability distribution, or two samples. For brevity, for a two-sided case, the null hypothesis is defined as the maximum distance between the two cumulative distributions. If this distance is greater than the critical value of the Smirnov table, $S_{m,n,1-\alpha}$, for parameters m, n , and $1-\alpha$ (where α is the significance level), then we can reject the null hypothesis of no difference between the two distributions.

Likelihood Ratio Test

The likelihood ratio test is commonly used in the field of transportation to compare the goodness-of-fit of two models developed on the same sample for different sets of parameters (one set being a subset of the other one, Θ_1, Θ_2). In this case, $LR = -2(LL(\Theta_1) - LL(\Theta_2))$, and LR follows a χ^2 distribution with degree of freedom $m = |\Theta_2| - |\Theta_1|$.

Lognormal Distribution

A random variable follows a lognormal distribution if its values are equal to the exponential of another random variable that is normally distributed.

Lognormal distribution is commonly used in the mixed logit formulation of discrete choice modeling where a specific sign is expected for a variable (such as price and travel time). The PDF of X as a random variable with lognormal distribution is:

$$f(X = x) = \frac{1}{\sigma x \sqrt{2\pi}} \exp\left(-\frac{(\log(x) - \mu)^2}{2\sigma^2}\right),$$

Where μ and σ are mean and standard deviation of $\log(x)$.

Markov Chain Monte Carlo

Markov chains are commonly used to predict the next stage of a variable/system/agent conditional on its current state. Therefore, transitions are random and conditional on the distribution of the current state of agent/system/variable.

Borrowing concepts from the Markov chain approach, the Markov chain Monte Carlo (MCMC) approach is typically used to estimate a hard-to-estimate expectations like $\sum_{m=0}^M x(\tau^{m_0+m}) f\left(\frac{\tau^{m_0+m}}{M}\right) \cong \int x(t) f(t) dt$, where f is the PDF of x , but challenging to draw from. In such cases, the MCMC approach is used to generate a sequence of random draws (a Markov chain) to approximate f and eventually $\bar{x}$. If the sequence of these random draws for a large M is defined as $\{\tau^m, m \geq 0\}$, and the initial m_0 draws are discarded for burn-in effect, the set $\{\tau^{m_0}, \dots, \tau^{m_0+M}\}$ can be used to approximate such that:

$$\sum_{m=0}^M x(\tau^{m_0+m}) f\left(\frac{\tau^{m_0+m}}{M}\right) \cong \int x(t) f(t) dt.$$

When $f(t)$ is available from which random draws can be easily obtained, it can be used to approximate $\bar{x}$ using the Metropolis–Hasting sampling, or Gibbs sampling which are popular MCMC approaches. Gibbs sampling is a special case of MH. Gibbs sampling is used when it is possible to directly sample from the conditional distribution. MH is used when the conditional distribution does not belong to recognizable families of distributions or when direct sampling from the conditional is difficult. Metropolis–Hastings sampling is useful for Bayesian procedures, but is affected by challenges such as inefficiency, tuning and serial correlation. In the context of MH algorithms, f is called the target density and g is called the proposal. The MH algorithm is formed in two steps. In the first step, a proposal is generated. In the second step, the proposal is accepted or rejected. If the proposal is Gaussian, the Random–Walk Metropolis algorithm is obtained. In this case, the proposal is $\hat{\tau}$ is sampled from $N(\bar{\tau}, \Sigma)$, where τ denotes the current value and Σ is a scale matrix. Then, the acceptance probability is calculated as $A = \min(1, f(\hat{\tau})/f(\bar{\tau}))$.

Mixture Models

To estimate heterogeneity in parameter estimation, it is common to use a combination of components of a distribution. For example, in discrete choice modeling parametric mixed logit models, and non-parametric/semi-parametric latent class logit models are widely used in disciplines studying individual choice behavior.

If decision makers' decisions are consistent with the random utility maximization assumption, a mixed random utility model such as the mixed multinomial logit/probit model can capture random heterogeneity distribution by marginalizing the discrete choice kernel over some mixing distribution which captures the unobserved tastes variation of the decision makers (Train, 2009). However, such an assumption might be requiring strict assumptions about the taste variation distribution.

Despite the aforementioned limitations, all mixture models follow the following formulation:

$$f(X, \beta) = \int f(X, \psi) d\beta(\psi).$$

Distribution β is called the mixing distribution, where mixture models of this structure can be parameterized over the parameter space of $\mathbf{B}$. When the mixing distribution has discrete components as p_i , $\sum_{i=1}^M p_i = 1$, the probability can be written as:

$$f(X, \beta) = \sum_{i=1}^M p_i f(X, \beta_i),$$

which is the same structure as latent class models with M classes.

Moving Averages

Time series can be transformed by taking averages of several sequential values. In a general two-sided averaging scheme, the original time series variable e_t can be transformed to μ_t with order k as:

$$\mu_t = \frac{1}{2k+1} \sum_{i=-q}^q e_{t+i}.$$

When μ_t is defined for one side, that is, dependent on the past, and it is weighted by parameters, say θ_q , a MA model is constructed as:

$$\mu_t = \frac{1}{2k+1} \sum_{i=-q}^q \theta_i e_{t+i},$$

where $\theta_0=0$ and $\{e_t\}$ is white noise series. In this case, μ_t is observed and θ_i is estimated. The main difference between MA and the autoregressive model is that several instances of white noise appear on the right hand side while past instances of the dependent variable do not appear on the right hand side of the equation.

Multicollinearity

For crosssectional data, and more specifically for linear regression, multicollinearity violates some basic assumptions of OLS. When perfect collinearity exists, the model coefficients cannot be estimated, unidentifiability. When partial collinearity exists, typically, acceptable goodness-of-fit is obtained but there are not many statistically significant coefficients in the model. This might be due to pairwise correlation between the explanatory variables, which then results in wider confidence intervals with smaller t-values. Since multicollinearity is a sample data issue, if the purpose of model development is prediction only, then the small goodness-of-fit should not be an issue, and the model can be used with no changes. However, if possible, omitting highly colinear variables or combing and transforming colinear variables might be a useful technique to reduce the impact of multicollinearity.

Normal Distribution, Univariate, or Multivariate

Also called Gaussian distribution, normal distribution is the most commonly used distribution in statistics. With PDF as $f(X) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left\{-\frac{(X-\bar{X})^2}{2\sigma^2}\right\}$, it is noted that $X \sim N(\bar{X}, \sigma)$. This distribution is symmetric and unimodal with mean and median being equal.

When multiple random variables that are individually normally distributed are correlated, a multivariate normal distribution can be used. If X and Y are normally distributed with variances σ_X and σ_Y with covariance σ_{XY} then the joint PDF can be written as:

$$f(X, Y) = \frac{1}{2\pi\sigma_X\sigma_Y\sqrt{1-\rho^2}} \exp\left\{-\frac{1}{2(1-\rho^2)} \left[\left(\frac{X-\bar{X}}{\sigma_X}\right)^2 \left(\frac{Y-\bar{Y}}{\sigma_Y}\right)^2 - 2\frac{X-\bar{X}}{\sigma_X} \frac{Y-\bar{Y}}{\sigma_Y} \right] \right\},$$

$$\text{where } \rho = \frac{\sigma_{XY}}{(\sigma_X\sigma_Y)}$$

If more than two random variables are considered as $X=[X_1, \dots, X_n]$ $\rho = \frac{\sigma_{XY}}{(\sigma_X\sigma_Y)}$ as then the PDF of X can be written as:

$$f(X) = \frac{1}{\sqrt{(2\pi)^n |\mathbf{\Omega}|}} \exp\left\{-\frac{1}{2}(X-\bar{X})^T \mathbf{\Omega} (X-\bar{X})\right\},$$

where $\mathbf{\Omega}$ is the covariance matrix being equal to the expected value of $(X-\bar{X})(X-\bar{X})^T$. Then it can be said that $X \sim N(\bar{X}, \mathbf{\Omega})$.

Poisson Distribution and its Application in Transportation

Count data consist of nonnegative integer values. In the area of transportation there are several examples of such data such as: number of weekly/daily trips per person or household, number of driver route changes per week, number of trip departure changes per week, drivers' frequency-of-use of technologies for traveling per week, number of accidents observed on road segments per year. The most common count data models are Poisson and negative binomial regression models. Consider the number of accidents occurring per year at various intersections in a city. The probability of location i having Y_i accidents per year can be written as $P(Y_i) = \frac{e^{-\lambda_i} \lambda_i^{Y_i}}{Y_i!}$, where λ_i is the parameter of location i which can be parameterized as $\lambda_i = e^{\beta X_i}$ where X_i is a vector of attributes of location i . λ_i provides the expected number of accidents at i .

If parameterization of λ_i includes an unobserved random term, other than the attributes of location i , then λ_i can be re-written as $\lambda_i = e^{\beta X_i + \varepsilon_i}$. Then by assuming a gamma distribution for ε_i with mean 1 and variance σ , then the probability of Y_i can be rewritten as:

$$P(Y_i) = \frac{\Gamma\left[\frac{1}{\alpha} + Y_i\right]}{\Gamma\left(\frac{1}{\alpha}\right) Y_i!} \left(\frac{\frac{1}{\alpha}}{\frac{1}{\alpha} + \lambda_i}\right)^{\frac{1}{\alpha}} \left(\frac{\lambda_i}{\frac{1}{\alpha} + \lambda_i}\right)^{Y_i},$$

where Γ is the gamma function and α is the overdispersion parameter, and $\text{Var}[Y_i] = E[Y_i] + \alpha E[Y_i]^2$. This PDF with gamma distributed unobserved term is called negative-binomial function, which is commonly used in modeling accidents (Washington et al.,2010).

P Values

The p-value (the most commonly used value is 5%) is lowest level for rejecting the null hypothesis, while it is true. In other words, for a 5% P value, the chance of committing a Type I error (the probability of rejecting the true hypothesis) is 5 in 100. There are some confusions about P value such as:

- P value (or $1 - p$) measures the probability of the null hypothesis (alternative hypothesis) being true (or false);
- P value is to assess the importance, significance, generalizability or replicability of a result;
- P value is the rate of the Type I error.

Sample Size Determination

Sample size is typically determined in the field of transportation based on the required variance of a random variable (a dependent variable). Then the sample size can depend on three factors: (1) variability of the parameter in the population, (2) degree of accuracy required for the variable, and (3) population size. By considering a normal distribution for the mean of the variable (based on the central limit theorem) for a 5% acceptance level, we can write $-1.96 \times s < \bar{x} - \mu \leq 1.96 \times s \Rightarrow \frac{s}{\sqrt{n}} - 1.96 \times \frac{s}{\sqrt{n}} < \bar{x} - \mu \leq 1.96 \times \frac{s}{\sqrt{n}}$. Then it can be formatted as $d = |\bar{x} - \mu| \leq 1.96 \times \frac{s}{\sqrt{n}}$. Based on the highest acceptable value of d , let's call it w , the sample size can be estimated as $n = 15.36 \times \sigma^2 / w^2$. However, it is common that no information is available for w . Instead the relative ratio of w to the true mean is known $w' = w / \mu \times 100 \Rightarrow w = \mu \times w'$. Then the sample size can be estimated based on w' as: $n = 15.36 \times \sigma^2 / (\mu \times w')^2 = \frac{15.36}{w'^2} \times \left(\frac{\sigma}{\mu}\right)^2 = \frac{15.36}{w'^2} \times CV^2$ where CV is called the coefficient of variation (Ortuzar and Willumsen). If the population size is not large enough, then it should be adjusted as $n / (1 + \frac{n}{N})$.

Sampling Algorithms

Samples are used to represent the population. Therefore, it is essential to assure that the attributes of the population are reflected when using the sample. If we can afford having a large sample, a pure random sample can easily represent the population. However, there are several issues that may arise if a pure random sample is considered. First, there might be minorities from whom finding a representative sample would increase the overall sample size. Second, sampling is a costly process. For example, the cost of having household travel surveys is over \$200 for each completed sample. Therefore, it is crucial to maintain the sample size at an efficient level.

Stratified sampling is a commonly practiced approach to reduce the sample size while having representatives from minorities within the population. In stratified sampling random samples are obtained with specific sizes from each stratum. Then the overall sample is formed by pooling the strata.

Student's t-Tests

This test is a parametric test based on the t-student distribution. It is generally symmetric and flatter than the normal distribution.

For two random variables of $X_1 \sim N(0, 1)$ and $X_2 \sim \chi_k^2$ that are independent we can construct another random variable as $t_k = X_1 / \sqrt{\frac{X_2}{k}}$, which is called to follow Student's t distribution with k degrees of freedom. As k increases, the t distribution approximates the normal distribution.

This distribution is commonly used in regression models to test the null hypothesis of the estimated variables being any different than zero. In such cases, because the expected value of the estimated parameter is of interest, it is assumed that $\bar{\beta}$ is normally distributed and its standard deviation is unknown to be estimated using the sample. Then a statistic is formed as $\beta = \bar{\beta}/(S/\sqrt{n})$. Here S follows a χ^2 distribution and $\bar{\beta}$ is normally distributed. For large samples ($n \geq 30$) this statistic collapses to a normally distributed random variable.

Another application of t-student test is to compare the mean of two independent samples (with sample sizes of n_1 and n_2) by constructing the following statistic:

$$t_k = (\bar{X}_1 - \bar{X}_2) / \sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}},$$

which approximately follows a t-distribution with k being equal to the following:

$$\left(\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2} \right)^2 / \left(\left(\frac{s_1^2}{n_1} \right)^2 / (n_1 - 1) + \left(\frac{s_2^2}{n_2} \right)^2 / (n_2 - 1) \right).$$

Uniform Distribution

One of the most basic distributions has a fixed probability in an interval and zero otherwise. The general PDF has the form of: $f(x) = \{ 1/(U - L) \text{ if } L \leq x \leq U \}$ otherwise for values of the random variable in the $[L, U]$ interval the cumulative density function is $(x - L)/(U - L)$, and the expected value of this distribution is $(U + L)/2$.

Weibull Distribution

Weibull distribution is the most commonly used function in hazard-based modeling. The PDF of the Weibull distribution for positive values, with shape parameter γ can be written as $f(x, \gamma) = \gamma x^{\gamma-1} e^{-x^\gamma}$. Then the cumulative density, survival and hazard functions are written as $1 - e^{-x^\gamma}$, e^{-x^γ} , and $\gamma x^{\gamma-1}$.

Databases

Crosssectional Data

In one categorization, the most commonly used data for transportation modeling is called crosssectional data which is collected for a specific *crosssection* of time. Therefore, the temporal variation in such data is negligible. Household travel surveys are the most commonly used data sources of this kind which may be collected during a year or on a specific day of the year which is assumed to be a typical day (Meyer and Miller, 1984). Data on network (highway and transit) performance can also be collected for a section of time (Meyer and Miller, 1984) while it can be recorded for multiple time slots, which can be then used for time series modeling (Ma et al., 2015).

Panel Data

Panel data, also called longitudinal data, are datasets, where for multiple times, the same respondent/individual/subject is interviewed/surveyed. In transportation applications, respondents might be households, firms, individual persons, locations, network links or network nodes. The main advantage of panel data over crosssection data is that they can be used to study dynamics and variation of tastes of individuals over time. In a typical regression model $Y_{it} = \alpha + \beta X_{it} + \epsilon_{it}$ where t refers to the time periods and i refers to the individuals/respondents/etc. The random term in this case may not be simply iid, meaning that it can be split into two parts as $\epsilon_{it} = \epsilon_i + u_{it}$, where u_{it} is the random distance and is the time invariant unobserved effect of individual i . If it is assumed that $\epsilon_i \sim IID(0, \sigma_\epsilon^2)$ and $u_{it} \sim IID(0, \sigma_u^2)$, then the correlation between ϵ_{it} and $\epsilon_{it'}$ for the same individual is equal to 1 if t and t' are the same and $\sigma_\epsilon^2 / (\sigma_\epsilon^2 + \sigma_u^2)$, otherwise. Similarly, if another error term is considered in ϵ_{it} as $\zeta_t \sim IID(0, \sigma_\zeta^2)$ then for the same individual, the correlation between ϵ_{it} and $\epsilon_{it'}$ is 1 if t and t' are the same and $\sigma_\epsilon^2 / (\sigma_\epsilon^2 + \sigma_u^2 + \sigma_\zeta^2)$, otherwise. However, if t and t' are the same but we are interested in attributes of two individuals i and j then the correlation is between the error terms ϵ_{it} and $\epsilon_{jt'}$ and would be $\sigma_\zeta^2 / (\sigma_\epsilon^2 + \sigma_u^2 + \sigma_\zeta^2)$. It is straightforward to show that such random effect structure implies homoscedasticity with an additive variance format for the three/two random terms. Therefore, the correlation between individual and period effects can be captured using these correlation (variance, covariance) values. If not properly controlled for, the model estimations in presence of panel data can be biased.

Revealed Preference

In one categorization, the most commonly analyzed data in the field of transportation is called revealed preference data, which are collected from respondents about their choices in observed situations. In the area of travel demand modeling, preference of people with regard to the mode of transport, traveling route, destination, and time of day (or departure time) are commonly modeled using information extracted from revealed preference of travelers.

An important challenge before using revealed preference data is to complement the observed preferences with attributes of nonchosen alternates. For example, in the case of mode choice, people reveal that they select a specific mode of transportation, say car. However, to be able to develop a choice model, other competing alternatives and their attributes should be also available.

Self-reported alternatives, especially nonchosen alternatives' attributes are associated with perceptions of the respondent, therefore, it is common to obtain the attributes of all alternatives including the chosen one, from external sources such as the transportation model or Google API.

There are two main issues limiting the use of revealed preference data. First, revealed preference data reflect the real world as such the variation of variables are limited to context. For example, transit fare is typically set by authorities and does not annually change or possibly minimally changes. Therefore, when crosssectional data are collected limited variation on cost of transportation is observed depending what exists in the transportation system. In other words, for a specific trip cost of transportation does not vary for specific mode of transportation, or possibly changing with limited variance. Second, hypothetical scenarios cannot be studied using revealed preference data. For example, what would be the preference of travelers when a new highway is built in the city? Or how people react to emerging mobility options, such as driverless vehicles, when they are ubiquitous? These two issues can be controlled for by collecting stated preference data.

Stated Preference Data

To study hypothetical contexts or examine larger variance of alternative attributes which might be too costly to be examined in the real world, stated preference surveys are designed. Some of the alternatives may be hypothetical while one (or even more) of them be an existing one. Therefore, the main purpose for designing stated preference surveys is to observe how people trade off when attributes of alternative change to large extent compared to what exists out in the transportation network, or to explore their behavior when presented with policies which are entirely new.

There are three main types of stated preference surveys: contingent valuation, conjoint analysis, and stated choice. Contingent valuation deals with elicitation of willingness-to-pay in which respondents are typically asked to directly report their willingness-to-pay for new options or policies (Fagnant and Kockelman, 2015). In the conjoint analysis respondents are presented with several options/policies and are asked to rank them. The best-worst analysis can be considered as a special case of conjoint analysis. In the most commonly used type of stated preference surveys, respondents are presented with several alternatives among which they select the preferred option (it is also possible to select more than one in special cases depending on the context of the survey). The choice for selecting the preferred options is assumed to be made based on the utility that is expected to be gained through the attributes of the preferred option. The stated choice data are commonly used to develop models based on random utility maximization (Train, 2009). Full factorial, fractional factorial, efficient, and optimal designs are some of the popular methods to design stated preference surveys (Hensher et al., 2005).

Survival Data

Survival data measure time from an origin, which can be a reference point in time beyond which data are censored (left censorship) or from the birth of the respondent, until a particular event occurs or the end of the study (right censorship). The event can be related to a decision changing the lifestyle such as changing job or residential location (Ghasri et al., 2018), vehicle transaction decisions (Rashidi et al., 2011), generating an activity (Auld et al., 2011), or a change in the lifestyle such birth of a child (Jenkins, 2005).

Survival analysis or hazard-based models are formed around four primary functions: (1) *Failure function* is defined as the probability of failure before a specific time, (2) *Survival function* is defined as the probability of not failing before a specific time, (3) *Failure PDF* is defined as the probability of failure in a minuscule time interval, which is the slope of failure function (4) *Hazard rate*, which is defined as the conditional probability of failure at time t , given the fact that the failure has not occurred before this time.

$$f_0(t) = \lim_{\Delta t \rightarrow 0} \Pr \frac{(t \leq T \leq t + \Delta t)}{\Delta} t = \frac{\partial F_0(t)}{\partial t} = -\frac{\partial S_0(t)}{\partial t},$$

$$h_0(t) = \lim_{\Delta t \rightarrow 0} \Pr \frac{(T + \Delta t > t \geq T | T \leq t)}{\Delta} t = \frac{f_0(t)}{S_0(t)} = \frac{f_0(t)}{1 - F_0(t)},$$

where F_0 denotes the failure function, S_0 shows the survival function, f_0 represents the failure PDF, and h_0 denotes the hazard rate.

A nonparametric function of survival and hazard rate can be estimated for any dataset using Kaplan-Meier estimators (Jenkins, 2005). Nonparametric formulations are quite widely used in practice given their flexibility.

There are two defined methods to incorporate the impact of exogenous variables called proportional hazard (PH), and accelerated failure time (AFT) (Jenkins, 2005). In AFT, covariates are incorporated in the definition of failure PDF. In the PH models, the baseline can be separated from the covariate part and the hazard function follows the same distribution as the baseline hazard function. The PDF and hazard function of AFT specifications are provided follows:

$$f(t, x_i) = f_0(t) \exp \left(- \sum_{j=1}^J \beta_j x_{ij} \right),$$

$$h(t, x_i) = h_0 \left(t \exp \left(- \sum_{j=1}^J \beta_j x_{ij} \right) \right) \exp \left(- \sum_{j=1}^J \beta_j x_{ij} \right).$$

Introduction

Travel surveys used to support transportation planning and policy efforts. In a very basic sense, these surveys are used to understand the current and future demand for transportation. Data from the surveys feed directly into long-range transportation plans, travel demand models, and policy analyses, among other uses. While the methods and technologies used to conduct these surveys have evolved over time, the core data obtained remain largely unchanged.

The main types of travel surveys include household, establishment (or workplace), commercial vehicle, on-board transit, visitor, and special event surveys. Each survey documents the origin and destination of travel for one slice of the traveling public along with demographic, geographic, and attitudinal characteristics of the travelers. Household and on-board surveys are the most common. The following provides more details about each survey type.

Household Surveys

Household survey data form the core input into most travel demand models. These surveys document the origin, destination, purpose, mode, and time of daily travel for residents of a region. Over time, these surveys have evolved from capturing only the work trip, only auto trip, only travel by those ages 16+ to comprehensive inventories of travel by all members of participating households, using all modes and for all purposes (Weiner, 2008).

Household surveys typically document details about the household and its members (demographics), inventory the household vehicle fleet, sometimes capture attitudinal data on topics important to the sponsoring agency, then capture the specific travel of all household members for a specific travel period, which can range from one day to a week or longer. Most household surveys focus on documenting weekday travel during the spring and fall, when schools are in session. Some surveys, such as the 2017 National Household Travel Survey (FHWA, 2017) obtain travel details for 365 days (including weekends, summer, and holidays).

As the methods have evolved, so have the sampling frames. Telephone-based samples (such as random-digit-dial or RDD frames, then listed and unlisted telephone frames) migrated to address-based sampling (ABS) frames based on the US Postal System address delivery sequencing files. The ABS sampling frame is often supplemented now by frames of cellular phone numbers, consumer data (including name, email and address as well as other demographic details). Often the sampling approach calls for over-sampling specific geographies or behaviors to ensure a robust data set to support modeling. The surveys focus on populations not in group quarters, so supplemental surveys are necessary to understand travel behavior of military personnel living on base, university students living in dormitories, and the elderly in assisted living communities. Research is underway to evaluate how consumer data can be used to refine sampling plans, including using vendor-generate demographic characteristics about the households to target specific types of households (such as low-income household) for oversampling.

The current survey process follows a two-stage design: the recruitment survey obtains basic household, personal, and attitudinal data, and the retrieval survey focuses on capturing the travel behavior details. Over time, the design has varied from single stage to two-stage surveys. Earlier studies were conducted in person in one interview (thus a single-stage design). As the use of the telephone to conduct surveys became more commonplace, the single-stage survey was thought to under-collect travel data so the industry moved to the current two-stage survey. As response rates have continued to decline, professionals are testing the return to a one-stage survey with controls to mitigate the concerns of trip underreporting.

In the past, households were provided detailed travel diaries or logs to capture the details of their travel. While travel logs are still used in some surveys today, more emphasis is placed on the use of smartphones to passively capture travel details. The surveys offer phone, mail, and web options to complete, with more advanced surveys offering respondents the option to track their travel using a smartphone application (app). Smartphone apps use the built-in global positioning system (GPS) technology to capture the movement of the phone and algorithms are used to decode those traces into trips, which are then validated by the traveler. Most

travel log-based surveys collect data for a 24-hour period. The smartphone-based surveys collect data for 3–7-day periods, with supplemental surveys of one month or longer to capture the rarer long-distance travel that occurs infrequently.

As with most surveys in the United States, household surveys have experienced declining response rates, nonresponse bias (missing critical population segments), and increasing costs. Agencies traditionally have conducted the household surveys once a decade (funding permitting), spending sometimes up to \$1 million for a sample of less than 1% of the population. The cost of these large-scale surveys includes both the financial cost as well as the staff time that must be dedicated to getting up to speed on current methods and then managing the effort for about 1 year.

A more recent trend adopted by some agencies is to conduct smaller surveys more frequently (annually or biannually). For example, the Ohio Department of Transportation's current survey of 10,000 households is comprised of 10 annual surveys of 1,000 households each (Anderson et al., 2015). The Federal Highway Administration is undertaking a similar conversion of its long-standing National Household Travel Survey. Formerly conducted every 5–8 years since 1969 with national samples of approximately 25,000 households, plans are to conduct the NextGen NHTS every other year starting in 2002 with a national sample of approximately 7,500 households.

Establishment Surveys

The counterpart to household surveys is establishment or workplace surveys. These surveys capture details about the firm (number of employees, hours of operation, industry classification, location) and about the travel to and from that establishment by both the employees and customers. As compared to the household surveys, establishment surveys are rarely conducted in the United States. The two most recent establishment surveys were conducted in New York City and Phoenix, both in the 2014–16 time frame.

The establishment survey process includes recruiting the firm and assigning it to a specific data collection period (typically weekday operating hours during fall and spring when school is in session). On the actual survey day, physical counts are taken to document the “universe” of site visits, which are used to expand the survey data.

The surveys are conducted in person using tablet-based survey programs. The surveys are short, focusing on only a few key demographic characteristics and the trip to and from that location. Respondents are asked to locate their origins and destinations using real-time mapping features in the survey software. Employees may be offered the option to complete their survey online.

Sampling plans for establishment surveys are drawn from business-frames that are commercially available. The databases list each business in a region, its address, sometimes a contact person, along with the industry classification and firm size. For the recent Phoenix survey, the stratification included industry classification, size, and geography (FHWA TMIP webinar, 2018).

There are two additional surveys often conducted as part of establishment surveys: special generator surveys and commercial vehicle surveys.

- Special generator surveys are establishment surveys conducted at locations that tend to be high volume and specialized in terms of their impact on regional transportation. Often, these surveys focus on hospitals, universities, shopping malls, and sporting venues. The same type of data are collected in terms of person counts and in-person intercept surveys. Some agencies have successfully used passive data products to capture travel associated with specific sporting events. The passive data provide comprehensive origin-destination details and an imputed trip origin (home) location but tends to lack any demographic details about the traveler. This issue is discussed more in the next session.
- Commercial vehicle survey—these surveys collect the detailed daily travel made in commercially owned vehicles, including a range of vehicle fleet from automobiles to vans and light-, medium-, and heavy-duty trucks. As with household surveys, the detailed paper logs are being replaced with smartphone apps. Unlike household surveys, some commercial vehicle surveys consist of obtaining administrative data from a company representative and fusing that to GPS-data already collected in the company-owned vehicles.

Transit On-Board Surveys

The most common mode-specific survey is the transit on-board survey. This survey focuses on the rider-reported usage of the transit system, including boarding and alighting locations as well as ultimate origins and destinations of travel for a specific transit trip. Supplemental demographic data are collected and sometimes a few attitudinal questions are also asked, space permitting. Because the survey is conducted on-board the transit vehicle or as intercepts while riders are waiting for the vehicle to arrive, the surveys are short and focused.

The methods for this type of survey are transitioning from in-person paper-based administration to in-person tablet administered surveys. In addition, agencies and researchers are mining fare card data and turnstile transaction data (where available) to obtain the overall O-D flow patterns (Zalewski et al., 2019).

The Future of Travel Surveys

With the availability of passive data products that summarize origin-destination flows in and about a specific region for a much lower cost than a traditional survey, the role of travel surveys is changing. In this section, the future of travel surveys is explored by

first reviewing the challenges, then the opportunities. Three examples of how passive data products have changed the travel survey landscape include the end of cordon line surveys, the quest for long-distance travel data, and the application of passive data to capture visitor and special event markets.

In the past, cordon line surveys (also called “external station surveys”) were conducted to capture details regarding trips entering a region, either to a destination within the region or to pass through the region en-route to another destination. This type of trip is important, as it influences traffic volume counts as well as congestion levels but is not captured in the household, establishment or transit surveys. Cordon line surveys were conducted roadside, by intercepting drivers at or near the regional boundaries. Drivers were asked a short series of questions to capture origin and destination of travel, trip purpose, vehicle occupancy, and, if commercial, cargo.

As traffic volumes increased, safety concerns led to the end of this practice and transportation planners turned to technology. First, roadside interviews were replaced with “license plate capture”—cameras that recorded vehicle license plates, which were then transcribed and matched against state vehicle registration records. Recorded plates were compared across capture points to determine if the vehicle exited the area and if so, time stamps were used to determine duration of time spent in the region. The cost of transcribing the license plate data led researchers to install portable Bluetooth readers along major routes to capture unique device identification numbers. Those details were matched across collection locations (similar to the license plate capture analysis) to determine if trips were to a local destination or through travel.

As analysts mine the passive data products to identify through versus local travel, the research has expanded into using the data to better understand travel patterns among low incidence travel groups, most notably long-distance travelers and special event travel. Using imputed home location of each device, researchers can identify when a device is used outside the home region and for how long. This data can be used to understand patterns of long-distance travel. In addition, by focusing on specific locations on specified dates and times, researchers can evaluate travel surrounding special events. These special events can be sporting events, community events, and even disasters.

The more these passive data products are used for known applications, the increased likelihood that more applications will be identified. The passive data products “narrow but deep,” meaning that there are only a few variables in these data products but a large volume of cases. Travel surveys, on the other hand, are “wide but shallow,” meaning that the data collected is significant (often hundreds of variables in the data sets) but the sample sizes are small (ranging from 1,500–25,000 households). Research is underway to evaluate the best methods for fusing these products and to identify alternative uses for both data sources. While some believe the passive data products, most working in this specialty see the passive data products as explaining the “why”—the traffic volumes, the origin-destination pairs, etc. However, for the “why” and the underlying demographics that explain travel behavior, the travel surveys remain the only option and thus are expected to continue to be administered.

Biography

Dr. Stacey Bricka has 30 years of experience in travel behavior research and analysis, travel surveys, and associated survey methods and emerging technologies and data sources. She is known for her extensive and innovative contributions to the state of the art in travel behavior methods, technologies, and analyses. She has managed or directed more than 100 surveys pertaining to travel behavior and transportation in general and moderated numerous conference sessions aimed at advancing the integration of passive data into travel behavior data programs for transportation agencies. She routinely advises agencies on various methodological and technological aspects of travel surveys and leveraging complementary passive data products. Dr. Bricka currently supports FHWA’s NHTS program, including the NextGen NHTS design activities. Her research priorities currently focus on integrating traditional travel survey data with emerging passive data sources. She holds a PhD in Community and Regional Planning from the University of Texas at Austin.

Travel demand models are analysis tools used in a variety of transportation planning studies. These models began to appear in the 1950s, and the analytical approaches have become more sophisticated as they took advantage of research in such fields as behavioral analysis, statistics, and operations research, as well as increases in computational power (Boyce and Williams, 2015). They are used in short and long-range transportation planning, analyses of proposed transportation infrastructure investments, public policy analyses, and studies of the effects of changing demographics and technology on transportation system use.

The first models were developed for use in large cities and metropolitan areas at a time when many jurisdictions were investing heavily in transportation infrastructure and needed tools to evaluate various policy and construction options (Committee for Determination of the State of the Practice in Metropolitan Area Travel Forecasting, 2007). Over time, models began to be used in a wider group of geographic contexts, ranging from relatively small areas to long distance interurban areas or corridors, and even entire countries, states, or provinces. The types of analytical methods used in the models became more varied in response to the various analysis contexts.

Moreover, the types of analyses for which travel demand models are used have evolved, as many mature jurisdictions began to focus less on large infrastructure projects such as new highways and more on smaller scale improvements and efficient use of existing transportation systems. In many places, there are statutory or regulatory requirements for transportation planning that affect analyses for which travel demand models can be valuable tools. For example, the United States requires that metropolitan areas that are designated as not meeting air quality goals must demonstrate that transportation plans conform to plans for meeting statutory standards. Recently, some jurisdictions have set ambitious goals for reducing carbon footprints that could require substantial changes in the ways that people travel.

Other transportation planning issues that have emerged since the first travel demand models appeared include the following:

- investment in new urban rail systems (models first emerged during a time of disinvestment in urban rail);
- an increased interest in managed lanes and priced roadways, especially dynamic pricing that varies by time of day and/or demand level;
- interest in promoting active transportation modes such as walking or bicycling, as a means of reducing vehicular congestion and emissions of pollutants, as well as improving public health;
- the emergence of transportation network companies (TNCs) that use mobile technology to match riders with drivers;
- the emergence of “micromobility,” or shared vehicles such as bicycles, scooters, and automobiles available in public settings that make use of remote payment technology; and
- the recognition that autonomous vehicle technology will soon make automobile travel available to persons who do not drive or who prefer to use their in-vehicle time doing something besides driving.

Summary of the State of the Practice

The state of the practice in travel demand modeling appropriately varies depending on the application context (Committee for Determination of the State of the Practice in Metropolitan Area Travel Forecasting, 2007). Larger problems, naturally, require more sophisticated tools, and so in many parts of the world the models in large metropolitan areas, as well as some larger scale models (national and statewide), use more complex approaches (though older, simpler practices persist in some countries). The state of the practice can be briefly summarized as follows:

- On the demand side, in larger planning areas with complex issues to analyze, disaggregate activity-based models (Castiglione et al., 2015) can be considered the state of the practice. In smaller planning areas where the issues do not require as detailed

analysis, aggregate trip-based models (Ortúzar and Willumsen, 2011) are used. In some larger areas, the older aggregate approaches are still in use.

- On the network assignment side, the state of the practice is still to use aggregate, static assignment procedures (Cambridge Systematics, Inc. et al., 2012) in most contexts. While disaggregate dynamic traffic assignment (DTA) (Chiu et al., 2011) approaches have existed for many years, they are not widely used in large regional contexts; they are more frequently applied for smaller areas or corridors.

In disaggregate approaches, typically the activities and travel choices of individual agents (persons, households, vehicles) are individually simulated; when aggregate results are required, the results from the individual simulations are summed. In aggregate approaches, the traveler population is segmented into a relatively small number of groups, and the travel made by each segment is modeled in an aggregate manner.

Travel Demand Model Components

Regardless of whether the underlying model uses an aggregate or disaggregate application approach, it is useful to consider the major components of a travel demand model using the concepts of the demand side and the supply side. Highway, transit, pedestrian, and bicycle networks, which are spatial representations of the transportation system in the model region, comprise the supply side of travel demand models. Highway networks include the locations and characteristics (such as capacities and speeds) of roadways. Transit networks represent the bus and rail systems (routes, stations, transfer points, and supporting parking facilities). In a general sense, the outputs of travel demand models that are used for planning purposes are facility level volumes (persons or vehicles). For vehicular travel, these volumes represent the number of vehicles using roadway segments in the model's highway network. For person travel, the volumes represent individual persons using public or private transit systems, walking, or bicycling.

Most personal travel is not truly a good that consumers desire but rather a means of reaching different locations where activities, such as working, education, shopping, recreation, or personal business, are performed (Castiglione et al., 2015). Early models (as do many current models) treated travel as a good to be consumed; many recent models treat the activities people wish to undertake as the desired goods and simulate the need for travel as a derived demand. Either way, the amount, locations, times, and modes of travel represent the demand side of models.

Representing the demand side of the model means simulating the movement of persons and goods throughout the region along the networks. Whether the travel is modeled directly or as a derived demand from activity undertaking, the demand side estimates the amount of travel (how many persons are traveling), the locations (origins and destinations of trips or journeys), the modes used to travel between origins and destinations, and the times at which the persons are traveling. This process is necessarily an oversimplification of the complex ways in which people make decisions about whether, where, how, and when to travel. It is impossible to model the myriad factors (some of which cannot be quantified easily) that affect human travel behavior decisions and the interactions among travelers, especially within households, that influence these decisions.

The vast majority of travel demand models simulate travel for a typical weekday (Cambridge Systematics, Inc. et al., 2012), in many cases segmented into different time periods within the day. Depending on the type of model, the demand components of the model may consist of the following components:

- characteristics of the traveler population, such as auto ownership;
- the amount of travel made by individuals in the travel population or in an activity-based framework, the number of activities requiring travel to their locations;
- the locations of the activities or the travel locations (trip ends);
- the modes used to travel between origins and destinations; and
- the time of day at which the travel takes place, or when the activities requiring travel begin and end.

The final step in the modeling process is assignment, which performs route choice using the supply side of the model (networks) for the trips simulated on the demand side of the model. All models perform highway assignment for automobile and truck trips; in regions where transit is a significant component of travel, transit assignment is also performed. The units for highway assignment are vehicles, or vehicle trips, while the units for transit assignment are persons, or person trips using transit. While there are a few recent applications where pedestrian or bicycle trips are assigned to networks, in most models these trips are not assigned.

A travel demand model produces a set of outputs that can be used for further analyses, based on a set of inputs that can be more readily obtained or estimated. There are two basic sets of inputs to the model:

- The transportation networks, from which estimates of travel distances, times, and costs can be obtained, and
- Socioeconomic and land use data, which are used to quantify the size and characteristics of the traveler population and to identify the relative attractiveness of various locations to which people might travel. Usually, these data are aggregated to "zones"—typically a model region has hundreds or thousands of zones—but in some cases, more detailed geographic resolution is used.

There are also a few data inputs that are technically not part of either of these two categories. These include fuel and other auto operating costs and geographically specific parking costs, which are not strictly tied to the transportation networks.

While it is recognized that travel behavior is a complex set of interconnected choices, travel demand models separate those choices into individual components so that the estimation of travel demand is a tractable problem. This means that the choice model components are applied sequentially, and while the effects of downstream components can affect upstream choices in simple, aggregate ways, for the most part the effects filter mainly in one direction.

Demand Model Components and Their Parameters

Travel demand model components use mathematical formulations to relate the model outputs to the model inputs (which often include outputs of previous components in the model sequence). The type of mathematical formulation varies depending on the particular component and the overall structure of the model. Commonly used formulations include simple factoring, linear regression, discrete choice (multinomial, nested, or ordered response logit, or probit) (Ben-Akiva and Lerman, 1985), and hazard duration.

The parameters for each model component may be estimated using observed travel behavior data, such as travel surveys, or asserted based on previous experience in the model region or elsewhere. Both estimation from observed data and assertion are common practices. When parameters are estimated, statistical methods are used to produce the estimates using maximum likelihood or other optimization processes.

When parameters are asserted, it is typical to use values from other contexts, such as similar areas to the model region, or averages of parameters from multiple contexts. One of the main motivations for asserting parameters is that the data to estimate parameters may not be available and may be difficult or expensive to collect. The sample sizes required to obtain statistically significant parameters given the population segmentation used in the model can be quite large. Despite the widespread use of transferred parameters, there is not strong evidence that model parameters are truly transferable in all cases (Rossi and Bhat, 2014).

Trip Assignment Methods

Highway assignment methods are based on estimating least cost paths between trip origins and destinations. Most of the cost is attributable to travel time; however, other costs, notably toll charges, may also be considered.

Because aggregated highway trips can cause congestion and therefore affect roadway travel times, it is not possible (except under uncongested conditions) to simply calculate shortest paths and allocate all trips to these paths. It is therefore necessary to consider the effects of congestion on travel times by relating traffic volumes, capacities, and travel times. Since driving behavior is complex and varies substantially among drivers, and because network representations in models do not consider all roadway characteristics that can affect travel time and capacity, these relationships are necessarily simplified. It is also important to note that travel times vary within assignment periods, and many drivers choose routes based on considerations other than minimizing costs (e.g., route reliability); having to ignore these effects further oversimplifies the route choice process.

There are two main approaches to highway assignment, static assignment (Sheffi, 1985), and dynamic traffic assignment (Chiu et al., 2011). In static assignment, origin-destination trip matrices are loaded onto the highway network, usually for various subperiods of the modeled day (e.g., the morning and afternoon peak periods). The most common static assignment approach is user equilibrium, which is based on Wardrop's principle that drivers choose to minimize their own costs, and equilibrium is reached when no driver can improve her travel time by switching routes (Wardrop, 1952). Model users can determine the settings for the assignment process (e.g., the function relating travel time to volume and capacity) using the modeling software. The main limitations of static assignment include the following:

- A quite limited set of network characteristics (facility type, area type, and number of lanes) is available for use in calculating capacity, and considerations such as signal timing and phasing, turning lanes, parking, and pedestrian activity are usually unavailable.
- The travel time on each link is computed using the volume and capacity for only that link, and interactions among individual highway links (downstream queuing, turns across oncoming traffic) are not considered.
- Volumes and travel times are averaged over the course of the assignment time period; variations in demand across the period are not considered.
- There is no requirement that demand not exceed capacity; all trips in the period must be loaded onto the network.

DTA methods directly simulate the movement of vehicles through the network over time. DTA can consider additional network characteristics, including turning lanes and signal timing (though maintaining all of this information for large networks can be problematic). In DTA applications, vehicles are processed through the network respecting capacity constraints and interactions with other vehicles. This allows them to simulate queuing when all demand cannot be processed through specific points in the network.

Despite the advantages of DTA over static assignment, its use is mainly confined to area or corridor studies rather than the large metropolitan regions (or bigger areas) for which many travel demand models are applied. There are several research-oriented examples of regionwide DTA applications, but they have been associated with long run times and insufficient data for proper application and validation (though in some cases input data are synthesized). Static assignment remains the standard practice in most urban area travel demand models.

Although there has been research into dynamic transit assignment methods, the transit assignment methods used in existing travel demand models are static. In models of areas where transit crowding can affect path choices, capacity constraints may be introduced.

Model Validation

Validation of a travel demand model is an essential step in ensuring that the model can produce reasonable outputs for the planning analyses that it will be used for (Cambridge Systematics, Inc., 2010; Pendyala and Bhat, 2008). Model validation generally consists of:

- comparisons of model results for a scenario that represents conditions that can be observed to empirical data for these conditions;
- reasonableness checks of model results in cases where the information represented by outputs cannot be observed; and
- tests of the sensitivity of the model to changes in inputs that represent the types of scenarios for which the model will be applied.

Model Application

Travel demand models are applied using specialized software packages, usually on personal computers or servers, or, more recently, using cloud-based services. In the early days of models, when mainframe computers were the only hardware options, the United States federal government, specifically the Urban Mass Transportation Administration (now the Federal Transit Administration) and the Federal Highway Administration, developed the Urban Transportation Planning System, a software package designed to apply the four-step modeling process. As personal computers came into common use in the 1980s, proprietary model application packages developed by private companies began to appear. Such packages are still in common use although they are often supplemented with custom software built for particular applications or, more recently, open source software that can be adapted for specific models. The latter are often used in the application of activity-based and other advanced travel demand models.

The sequential nature of model application results in some dilemmas in cases where choices may affect one other. For example, travel demand in a corridor depends on the travel times in the corridor, but these times are affected by the level of demand if the corridor becomes congested. To compensate for this, models are often applied in an iterative manner, where the inputs to demand side components are updated based on the travel times results from the highway assignment. In theory, the iteration continues until “convergence,” that is, when the output travel times are equal to the inputs; in practice, due to model run time considerations, the process is often truncated prior to true convergence.

Four-Step Modeling

Until the 1990s, the “four-step” modeling approach was ubiquitous (Boyce and Williams, 2015), and it remains the most commonly used approach. The four steps refer to trip generation, trip distribution, mode choice, and trip assignment—the first three steps representing the demand side. Four-step models are aggregate in nature, meaning that large segments of the traveler population are modeled together. As a result, it is not possible to identify travel behavior for individuals or for groups smaller than the segments used in the model. Spatial resolution is nearly always at the zone level.

Four-step models are trip-based, meaning that they model trips between two points without considering stops along the way (a stop would result in the end of a trip, after which a new trip would begin). Trips are modeled without consideration of other trips made by the same person.

The four-step process can be summarized as follows:

- Trip generation—Trips are segmented by purpose; usually there are three to eight purposes, such as home-based work, home-based shopping, nonhome-based, etc. Trip ends are classified as productions, which are the home ends of home-based trips, or attractions, the nonhome ends. Trip production models typically use crossclassification structures (Cambridge Systematics, Inc. et al., 2012), where the households in each zone are segmented by two or possible three dimensions, and the number of households in each zone is multiplied by an estimated or asserted trip rate. Trip attraction models are typically linear regression models relating the number of trips to the employment by type and the population in the zone.
- Trip distribution—For each trip purpose, this process matches up the trip productions and trip attractions to create trip tables (matrices) based on a formulation that relates the attractiveness of a zone to the number of attractions from the trip generation model and the impedance (time, cost, and/or distance) from the production zone. The model parameters relate the attractiveness of a zone to the impedance. Early models used the gravity model, an aggregate procedure where the productions for each zone are allocated to attraction zones based on the attractiveness function. While gravity models are still popular, most larger four-step models use multinomial logit trip distribution models, usually called “destination choice” or “location choice” models, where the attractiveness of each destination is represented in a logit utility function. The outputs of the trip distribution process are production–attraction trip matrices representing the total person trips for each purpose.
- Mode choice—The person trip table outputs from the trip distribution step are split into trips by mode, including various types of auto, transit, walk, and bicycle travel. There could be anywhere from two to a few dozen modes; these represent various submodes, including auto occupancy levels as well as transit types and access/egress modes. Typically, mode choice uses a nested

logit formulation although multinomial logit is often used when there are few modal alternatives. Besides the trip tables, other inputs can include the level of service (time, cost, number of transit transfers, etc.), traveler characteristics, and land use related variables. In the mode choice step, auto vehicle trip tables and transit person trip tables are produced at the origin-destination level for use in assignment.

- Trip assignment—Four-step models use static, aggregate assignment procedures, consistent with the aggregate outputs from the demand side.

While some models assign trips for the entire weekday, in most four-step models for larger regions, trip assignment (at least highway assignment) is usually done for several periods shorter than the entire modeled weekday. At some point in the process (the point varies by model), the daily trips or trip tables are divided into trips for each of the time periods used in assignment.

Activity-Based Modeling

Activity-based models (Bowman, 1998; Castiglione et al., 2015) have several fundamental differences from four-step models:

- The demand side is disaggregated; the activities for each person in the population are explicitly simulated.
- Travel is simulated as a way to accommodate the spatial and temporal differences in activity locations and timing.
- Since each person's activity pattern is simulated, the interdependencies among a person's trips are considered.
- Activity-based models are tour-based, rather than trip-based. Entire tours starting and ending at home or work are simulated as individual units, followed by simulation of the trips (stops) that comprise the tours. In other words, trip chaining is explicitly considered.
- In most activity-based models, the major interactions among members of households are considered (e.g., joint tour making among multiple household members, or escorting children to and from school).

There is more variation among the structures of different activity-based models than is the case for four-step models. Some basic features common to most activity-based models include the following:

- Synthetic population—This is generated to represent the true population of the model region. It is used as the basis for the simulation of individual activities and travel. The synthetic population is generated using fitting methods based on control totals that represent the assumed or observed demographics in the modeled scenario, with seed distributions often coming from large sample surveys (in the United States, the American Community Survey is often used).
- Long-term choices—These components represent choices or characteristics of the population that do not vary from day to day. Examples include vehicle ownership, workplace and school location, and, in some models, characteristics of the members of the population such as income levels and worker/student status. Common model forms include various discrete choice formulations though simpler methods are sometimes used.
- Activity generation—The set of activities performed by each individual in the population is simulated; this process considers the traveler's household structure and, in many models, the activities undertaken by other household members. These components are among the more complex in activity-based models due to the various spatial and temporal constraints on activity patterns. Common model forms include multinomial logit and multiple discrete-continuous extreme value. Activity generation is roughly equivalent to trip generation in four-step models though is far more complex.
- Activity timing, location, and mode of travel, and generation of stops on tours—In this series of components, the timing of activities (start and end times/durations), their locations, and the modes used to travel from home on the associated tours are simulated. Again, the spatial and temporal constraints on the various activities and the travel between their locations are considered. Common model forms include multinomial, nested, and ordered logit as well as (for time of day choice models) hazard duration.
- Stop locations and timing, and travel modes between stops—These models simulate the activities that take place at intermediate stops on the tours previously simulated. They are somewhat similar to the tour level components, but the alternatives are heavily constrained by the previously simulated tour level choices.

The outputs of the demand side simulation are tour and trip rosters, including the origins, destinations, times of day, and modes of the tours and trips; the characteristics of the travelers who make them are known and are included in the rosters. These rosters represent all of the personal travel in the model region made by residents of the region. Despite the disaggregate approach on the demand side, most activity-based models use static aggregate assignment procedures. This means that the trip rosters must be aggregated to create trip tables for assignment. There have been several research efforts into the integration of disaggregate demand DTA models, but these models have not yet made it into mainstream application.

How and Where Different Modeling Approaches are Used Today

While no model is a completely accurate depiction of behavioral reality, activity-based models are more realistic since they consider more of the factors that affect behavior and travel choices than four-step models do. Four-step models ignore the interactions among

multiple trips made by the same person (trip chaining) and among members of a household. Activity-based models are also more flexible because they are disaggregated; not only can a richer set of variables be considered (since there is no need to estimate statistically significant models for each of a large set of market segments defined by multiple variables), but the disaggregate outputs can be summarized using any variables used in the model. For example, outputs can be summarized by income level, geographic subregion, vehicle availability, ethnicity, age, or gender.

Despite these advantages, four-step models are still much more common than activity-based models. The latter can be more expensive to develop and maintain, and model run times are longer due to the increased computation required. In addition, their complexity relative to four-step models can make it more difficult for many practitioners to develop and maintain them, especially in contexts where planning resources are tight. Even though activity-based models have been used for more than two decades, they are still relatively new in many places. Furthermore, for many applications the simpler four-step model provides adequate information, especially for smaller, less diverse modeling environments.

Presently, activity-based models are used in most of the large metropolitan areas in the United States, as well as in many other countries around the world such as the Netherlands and Israel. In many countries, the four-step approach is still the standard, as well as in most smaller planning regions throughout the world.

Addressing Emerging Issues

While the types of planning analyses for which model results are used has evolved over time, recent years have brought an even greater pace to the changing needs of modeling. This is a direct result of changes in the way transportation supply is provided (e.g., open road tolling, TNCs, micromobility) as well as anticipated “game changers” such as autonomous vehicles. Additionally, traveler behavior may be changing as many cities are experiencing increases in residential development in or near downtowns, and greater percentages of the population are older. Furthermore, as computing power has increased, models can more feasibly deal with finer levels of detail in demographics and temporal and spatial resolution.

The aggregate nature of four-step models makes it difficult for them to adequately deal with these recent and expected changes in transportation service, which affect travelers at an individual level and can have substantial impacts on things like auto ownership. This makes activity-based models better suited to deal with these changes. However, the effects of these changes may be of greater planning significance in larger, more diverse planning environments, where activity-based models are already more likely to have been implemented, and smaller regions may choose not to invest in more sophisticated models to address them.

A modeling-related topic that has been gaining attention recently is dealing with forecasting uncertainty. Whether they are applied in an aggregate or disaggregate manner, travel demand models are essentially deterministic. It has always been recognized that the point estimates that models output have a degree of uncertainty that is unquantifiable since the error associated with much of the model input data (such as demographic or cost forecasts) as well as with the model parameters and the data used to estimate them may not be easily quantified.

In recent years, there has been increasing recognition of the effects of uncertainty around forecasts on planning decisions, especially as the effects of changes in transportation supply and travel behavior are becoming more difficult to predict (e.g., due to the introduction of autonomous vehicles). There have been efforts to incorporate risk analysis into the ways in which models are applied, through means such as exploratory modeling analysis. New tools are being developed that can work with existing models of different types to estimate probabilities of outcomes and of performance measures being achieved.

Introduction

Travel demand forecasting models have been developed to aid in short- and long-range transportation planning efforts in metropolitan areas around the world for more than 50 years. Over the past few decades, travel models have become increasingly sophisticated – both in terms of the behavioral processes that they seek to represent and in terms of the methodological approaches to model and predict activity-travel patterns. In the recent past in particular, travel demand forecasting models have increasingly strived to predict household and person activity-travel patterns by microsimulating individual mobility choices and movements through time and space, while explicitly recognizing the many constraints and opportunities that govern these behavioral phenomena. These models, often called activity-based or tour-based models, are increasingly being implemented in metropolitan areas around the world. At the same time, more traditional four-step travel demand models continue to be in wide use. More recently, the availability of big data – often constituting trajectories of millions of individuals collected through passive monitoring of cellular phone locations and movements – has made it possible to develop more data-driven modeling approaches and opened up new possibilities for validating the predictions of travel demand forecasting models.

Even though a variety of modeling tools are increasingly finding their way into agency practice, the principles of model calibration and validation are quite robust and applicable across modeling methods and platforms. When a travel demand forecasting model is developed, it is desirable to ensure that the model is able to replicate current base-year real-world conditions within an acceptable tolerance, and is able to provide forecasts of travel demand and activity patterns that are behaviorally intuitive, consistent with documented evidence (if available), and useful for planning purposes. It is in this context that this chapter purports to offer an overview of travel model calibration and validation methods, fully recognizing that these terms are often interpreted and use somewhat interchangeably in the profession.

Planning transportation investments and formulating transportation policies relies on the ability to model and replicate activity-travel demand under a wide variety of policy scenarios and system conditions. Travel models often have many components, covering the wide range of activity-travel and mobility choices that constitute travel demand. These may include choices such as activity generation, type of activity, timing (scheduling of activity), trip departure time choice, route choice, mode choice, destination choice, activity sequencing (trip chaining), activity duration (time use), and joint activity-travel engagement (accompaniment). The model components capturing each of these (and other) choices are then linked together, often with appropriate feedback loops, to comprise an entire travel model system. Each individual model component needs to be calibrated and validated in isolation, and the model as a whole needs to be calibrated and validated as well. Errors in calibration and validation of a specific model component could lead to downstream issues in the model chain, as the propagation of errors may will inevitably impact the accuracy and usefulness of the travel forecasts obtained from the model. Calibration and validation are therefore critical steps in the model development and deployment process.

This chapter is intended to offer an overview of travel model calibration and validation processes and considerations. The next section offers explanations of the various terms and a distinction between disaggregate and aggregate model calibration and validation. The third section identifies sources of error and uncertainty in the travel model calibration and validation arena. The fourth section offers an overview of calibration and validation of travel model components and the model as a whole. A few examples are furnished in this section as well. Because sensitivity analysis is a critical part of establishing the validity and usefulness of a model, a separate section is dedicated to sensitivity analysis. Finally, the chapter closes with a concluding section.

Key Terminology Related to Model Calibration and Validation

The model development and deployment process may be viewed as consisting of four major steps (Cambridge Systematics, Inc., 2010). This section offers an overview of these steps with a view to help delineate the steps and draw a distinction between calibration and validation. Although there may be slightly differing definitions and interpretations of these terms in the literature

and model documentation, the essential distinctions are well-recognized and the descriptions presented in this chapter are quite generalizable to most model development efforts.

The first step in the model development process is model estimation. Model estimation (which is not within the scope of this chapter) involves the calculation of model coefficients, parameters, and goodness-of-fit statistics. This is typically accomplished using travel survey data sets, although secondary data sources may be used to augment and enhance the travel survey data set. A variety of statistical methods including regression-based techniques, discrete choice models, and other econometric methods are typically used to estimate coefficients and parameters. Model coefficients are calculated such that the model fits the data as closely as possible, with the fitting function defined by the specific econometric methodology being used. Model coefficients are often examined for their behavioral intuitiveness, relative magnitudes and signs, and potential sensitivity to changes in explanatory variables. Many different model specifications are often tested before a final model specification is adopted. In instances where a coefficient value consistent with expectations is not being obtained, or local data are sparse, the model developer may choose to assert a coefficient value; this is often referred to as coefficient assertion.

Model calibration (which is within the scope of this chapter) often involves the adjustment of parameters so that model predictions replicate observed patterns in the data set used to develop the models in the first place. Estimated or asserted coefficients may be used to predict distributions and averages of various mobility choices and travel characteristics (for the estimation data set sample) and compared against the observed distributions in the data set. This is similar to comparing a predicted value to an observed value in a regression modeling effort. The difference between these values constitutes a difference or an error that the model estimation step attempts to minimize in calculating the coefficients. Comparisons of predicted versus observed travel characteristics provide the ability to assess the extent to which the model fits the data. If a certain comparison is viewed as subpar, it is possible to change the specification of the model and re-estimate model coefficients with a potentially richer model specification. Even after repeated attempts at model specification fine-tuning, if the match between model predictions and observed sample characteristics is not deemed acceptable, then parameter adjustment and coefficient assertion may be done to “calibrate” the model.

Following model calibration, model validation is undertaken. Model validation may take a number of forms, with two key forms described here. First, model validation involves comparing model predictions to real-world conditions, where the real-world conditions are derived from external data sources not used in model estimation and calibration. A typical validation exercise may involve comparing predictions of traffic volumes on major corridors to observed traffic counts on those corridors for a comparable time period. In this case, the traffic counts are an external source of data and not used in the model estimation and calibration process to begin with. Similarly, transit boardings, alightings, and route-level ridership numbers may serve as an external data source to validate the predictions coming out of a travel demand model. Care should be exercised to ensure that the external data used to check the validity of a travel model are accurate and correspond to the outputs of the travel model in terms of spatial and temporal resolution. Sometimes, model estimation and calibration may be performed using a subset of a travel survey sample, keeping the hold-out sample for validation purposes. In this case, model estimation and calibration is performed on the estimation (sub)sample, and then the model is applied to the hold-out validation (sub)sample. The predictions are compared to observed characteristics for the validation sample to determine the ability of the model to replicate observed patterns in an independent sample; because this subsample was not included in the model estimation data set, some regard this effort as a model validation exercise. This would, however, require that the survey sample data set is large (thus offering a sizeable estimation subsample and a hold-out validation sample). In addition, even if such a validation exercise is conducted, it is advisable to perform additional validation checks against external data sources such as traffic counts, census journey to work flow data, and other secondary sources that are completely independent of the travel survey data set.

The second major element of model validation is sensitivity testing. The sensitivity of models to changes in input conditions can be assessed through the computation of elasticity measures (derived from coefficient values) and other metrics of interest (e.g., computation of value of time, or ratio of out-of-vehicle to in-vehicle time coefficient values, in a mode choice model) that convey the degree to which a model reflects tradeoffs in behavioral choice phenomena. In addition, sensitivity testing involves the application of models to many different scenarios defined by a variety of input conditions. Socioeconomic variables, network conditions, modal level of service attributes, and land use variables may all be changed to different degrees in various combinations; running the model on alternative hypothetical scenarios will provide useful insights on the ability of the model to provide behaviorally intuitive, reasonable, and useful forecasts for planning and policy making. In some cases (but not all), the degree of sensitivity exhibited by the model (to changes in inputs) can be compared against real world empirical evidence to check the validity of the forecast (e.g., Evans, 2004; Milam et al., 2017).

Another key aspect of model validation is the need to distinguish between disaggregate and aggregate validation. This distinction may be particularly drawn in the context of recent microsimulation-based activity-based models of travel demand. Such models often provide individual activity-travel patterns (records) as outputs. When interfaced or integrated with a dynamic traffic assignment (DTA) model, they are able to provide individual vehicle trajectories as they traverse the network from origin to destination. It is potentially feasible to check the validity of these individual activity-travel patterns and vehicle trajectories for their reasonableness. Activity-travel patterns should not violate laws of physics, spatio-temporal constraints cannot be breached (in most circumstances), children (under a certain age) cannot be left abandoned without adult supervision, and the same person cannot be at two locations at the same time. Similarly, the route, travel time, and speed associated with a vehicle trajectory on the network should be reasonable and consistent with real-world path choice behavior. Many of these checks can be performed to examine disaggregate level outputs and ensure that the model is producing patterns of travel that are plausible. This reasonableness and logic check is a critical part of disaggregate model validation.

Aggregate model validation applies to both traditional four-step travel demand models and newer activity-based microsimulation models of travel demand. In this case, aggregate measures of travel demand are checked against known external data sources that represent ground truth. Such external data sources may include census socioeconomic and demographic data, census journey-to-work flow data, traffic volume data, travel time and speed data, and regional measures of vehicle miles of travel (VMT), trip rates, and transit ridership. Comparisons of aggregate measures of travel demand output by the model with external data sources provides a means of determining whether the model is able to replicate overall patterns of travel within the specified time period, geography, and market segment of interest. Aggregate validation can be done for specific demographic and socioeconomic groups, specific corridors in the network, or specific geographical subareas or markets to ensure that the model is capturing the heterogeneity that may be prevalent in a region. Simple region wide comparisons may mask the variation that exists across markets, space, and time.

Sources of Error and Uncertainty in Travel Model Calibration and Validation

It should be recognized that there are a number of sources of error and uncertainty associated with travel model calibration and validation. These sources of error and uncertainty often contribute to the need for model adjustments so that model predictions more effectively replicated observed ground truth conditions. However, there may be instances where model validity checks can reveal underlying issues with the land use data, network coding, or travel survey data; the model developer can then fix underlying data issues without the need to make ad-hoc or arbitrary model adjustments. Before making corrections to a model specification through a calibration process, it would be advisable to first check all input data for any anomalies or issues and ensure that the data sets do not have errors that could adversely impact a model validation exercise. The sources of error and uncertainty are described in this section.

One of the key sources of error is the model specification error. Despite decades of research into traveler behavior and values across a myriad of disciplines, much remains to be learned about travel decision-making processes under different conditions. In addition, travel characteristics present both dynamics and stationarity over time, rendering it difficult to determine elements that should remain static versus those that should evolve. Model specification is an abstract representation (and an approximation) of traveler choice processes, and hence any calibration and validation exercise should involve a close look at the model structure, sequencing of model components, the causal decision hierarchy implied by the model component sequence, and the array and form of explanatory variables included in various model components. In addition, the forms of the statistical models should be also be revisited to ensure that the methodological approach to modeling different choice phenomena are appropriate.

There may also be errors in the validation data, that is, the secondary external data against which model predictions are compared. As noted earlier in this chapter, external validation data may include traffic counts, link/corridor volumes, speed, and travel time data offered by an external source, transit ridership, travel survey data, mobile phone trajectory data, and census socioeconomic and journey-to-work flow data. All of these data sets are used extensively in model validation exercises and hence it is critical to ensure that the methods used to collect and compile the data are appropriate, correct, and devoid of elements that could lead to biases in the data. Moreover, it is critical to have appropriate metadata so that details about the validation data are well-documented. In this way, it is possible to ensure that comparisons between model forecasts and validation data are appropriate and refer to the same time period, geography, underlying conditions, and output variable. In some cases, it may be possible to identify and correct errors in the validation data (or check against multiple sources) without having to make corrections to the model structure and specification itself.

Sensitivity analysis is a key component of any model calibration and validation exercise. When conducting a sensitivity analysis, it would be useful to construct a range of scenarios for which the capabilities of the model can be tested. Some scenarios should be constructed in such a way that the general magnitude and direction of change in the forecast is known by virtue of available empirical evidence or prior experience. For example, it is generally known how transit ridership responds to changes in fare or frequency of service. Similarly, it is likely that an area has some evidence (from the past) on how traffic volumes and travel times change when a lane closure occurs (say, in a workzone) or a capacity expansion project (e.g., addition of a highway lane) is accomplished. There is also evidence documented in the literature regarding changes in travel demand that result from changes in system conditions, and model forecasts (of change) can be compared against documented evidence to verify model validity.

On the other hand, there may be a number of scenarios for which real-world evidence is absent. This is particularly true in the context of emerging modes of transportation and mobility services, new traveler information systems and mobile apps, and futuristic transportation technologies such as autonomous vehicles. In such instances, there is no basis to determine whether a model forecast is reasonable or valid. In other words, there is considerable uncertainty as to how the market may adopt and adapt to the new mobility options, modes of transportation, transportation policy, or traveler information system. This uncertainty renders model validation difficult, especially when the model is expected to be used to forecast long-term transportation trends when new rapidly evolving technologies may find their way into the marketplace. The analyst should recognize the uncertainty associated with such scenarios and explain all of the assumptions underlying model applications involving future transportation technologies for which no past or current evidence or data is available. Appropriate reasonableness and logic checks may be applied to assess whether the model is generally offering forecasts consistent with behavioral intuition, but there is little basis to assess whether the magnitude of change is of the appropriate order.

Finally, as noted at the beginning of this section, there may be errors in the input data that drive the model estimation and development process. Models rely on a suite of input data sets including land use data, socioeconomic and demographic data

(census data, for example), travel survey data, and highway and transit networks (described by a series of attributes such as speeds, capacities, and link lengths). These data sets and the variables they contain are critical to model specification, estimation, and calibration. If any of these data sets have errors, the resulting model is likely to be erroneous and offer forecasts that are invalid (do not match ground truth) and do not pass reasonableness and logic checks. In that case, it would be of value to try and isolate the potential error in the input data sets and make necessary checks and corrections that may be warranted.

Calibration and Validation of Model Components and Entire Model System

This section offers a brief overview of calibration and validation of individual model components that are commonly found in most travel demand forecasting model systems. As noted earlier, most assessments of model predictions can be performed for specific market segments, times of day, purposes of travel, geographic (sub) areas, and network corridors or links. As long as observed real-world data about system conditions are available for these specific segments and markets, model validation can be conducted at the level of fidelity for which data is available.

Before embarking on any model development effort, it is important to check the validity of the input data that will drive the model development process. This may include travel survey data, land use and socioeconomic data, population census data, and highway and transit network data. Likewise, care should be taken to assemble and check validation data including traffic counts by time of day and vehicle type for key corridors and links, transit ridership data by route and time of day, travel time and speed data from third party vendors or detectors, and origin-destination flow data that may be available from external sources. In the interest of brevity, validation checks for these data elements are not described here, as this chapter focuses on calibration and validation of model components; details on checking validity of input and validation data are available elsewhere ([Cambridge Systematics Inc., 2010](#)). The remainder of this section will focus on key components of typical travel model systems.

1. Socioeconomic or Synthetic Population Models

Travel demand model systems rely on socio-economic data. In the case of activity-based microsimulation models, a synthetic population of the region is needed so that individual-level activity-travel patterns can be simulated. For more traditional four-step travel demand models, the socio-economic models usually aim to derive joint distributions of various socio-economic characteristics (household size, number of workers, household income, and vehicle ownership) based on available marginal distributions of such variables. The joint distributions may be derived through iterative proportional fitting (IPF) techniques or through the use of curves that represent population proportions of various subgroups. Synthetic population models aim to generate a population of agents for the region such that the characteristics of the synthetic population mirror those of the true population as captured in the census data. In either case, the resulting distributions of various socio-economic characteristics should be compared against census data or other socio-economic data that may be available from an external source. Checks should be made at the regional level as well as a more fine-grained spatial level, such as census tract, traffic analysis zone (TAZ), or census public use microdata area (PUMA). In the case of a synthetic population generation process, the resulting synthetic population should be checked (for validity) with respect to both variables that were controlled in the synthesis as well as variables that were not controlled in the synthesis. If the match to (important) uncontrolled variables is not adequate, then the set of control variables should be modified. Checks should also be performed by comparing multidimensional distributions against corresponding distributions derived from census sources.

2. Vehicle Ownership and Fleet Composition Models

Most travel demand model systems incorporate a vehicle ownership model that takes the form of a discrete choice model such as a multinomial logit or ordered logit/probit model. More recently, a few activity-based travel models are also incorporating multiple discrete-continuous extreme value (MDCEV) models of vehicle fleet composition and primary driver allocation (to each vehicle), so that vehicle type choice can be explicitly modeled. The calibration step would involve comparing model predictions (of distributions of vehicle ownership by socioeconomic or geographic market segment) against travel survey data and making adjustments to alternative specific constants to better replicate the distributions. Validation may be performed by comparing vehicle ownership distributions against external sources such as census data. A vehicle fleet composition model may likewise be calibrated against travel survey data, and validated against an external source such as data from a motor vehicle registration agency that may be able to share aggregate distributions of vehicle makes, models, and vintage in the region or subregion (e.g., zipcode) level. Measures of elasticity can be computed and sensitivity tests may be performed to ensure that the model provides appropriate levels of responsiveness when input conditions change.

3. Activity-Travel-Tour Generation and Daily Schedule/Pattern Models

Most travel demand modeling processes start with an activity, trip, or tour generation process. In traditional four-step travel demand models, cross-classification matrices of trip rates (by market segment) are computed or regression-based models of trip generation are developed using survey data. If regression-based models are adopted, then model calibration may be conducted by comparing predicted trip rates (for different markets) against observed trip rates in the survey data. Intercept terms may be adjusted and model specifications may be enhanced to better replicate observed trip generation rates for different socio-demographic groups. In the case of activity-based models, various schemes may be adopted to represent generation of travel. These may include activity generation, tour generation, or daily activity-pattern models (for different market segments). These models, often taking the form of discrete choice models, may be calibrated against survey data. For example, in a recent model validation exercise for the Baltimore Metropolitan Council (BMC) activity-based model (called InSITE), the model predicted that 41.2% of full-time workers make one work tour with no stops and 33.8% make one work tour (in the day) with intermediate stops. The corresponding values in the

expanded survey data are 42.6% and 31.5% (Cambridge Systematics Inc., 2017). Deviations between survey data and model predictions would necessitate model recalibration by adjusting alternative specific constants and asserting coefficients (as sparingly as possible). If minor adjustments are not able to yield an improved replication of observed behavior, then it is advisable to re-estimate the model with a richer specification and to check the survey data for possible errors, outliers, or illogical responses.

4. Location/Destination Choices

Both traditional four-step travel demand models and more recent activity-based travel models include an array of location and destination choice models. Location models often purport to identify work and school locations (which tend to be longer term location decisions) while destination choice models are intended to determine places visited for various activity and travel purposes (more day-to-day decisions). These models often take the form of multinomial logit models with appropriate size terms to ensure robustness regardless of how zonal systems are configured. In general, these models do not include alternative specific constants, but they may include calibration terms to help the models replicate observed patterns. Work location choice models can be calibrated to replicate work trip length distributions in the travel survey data set and validated against census journey to work flow data. Appropriate shadow price terms can be calibrated to help replicate work flow data and ensure that work trips are reasonably consistent with the number of jobs in each zone. Similarly, school location choice models can be calibrated using school trip length distributions in the survey data and validated against school enrollment data typically available from a Department of Education or similar external source. Destination choice models are generally calibrated such that observed (in survey data) and predicted trip length distributions are replicated for various trip purposes and market segments. Calibration terms may be introduced to help bring about closer matches in observed and predicted trip length distributions. Measures of closeness include the chi-square test to examine the significance of difference between two distributions and the coincidence ratio that measures the degree of overlap of two distributions. The coincidence ratio is formulated as follows:

$$CR = \frac{\sum_{n=1}^N [\min(P_n^m, P_n^o)]}{\sum_{n=1}^N [\max(P_n^m, P_n^o)]}$$

where,

CR = coincidence ratio

N = number of intervals in the distribution (e.g., time or distance bins)

P_n^m = proportion of modeled distribution in interval n

P_n^o = proportion of observed distribution in interval n

A coincidence ratio of 1.0 indicates a perfect match while that closer to zero indicates a poor fit or match of trip length distributions. In general, coincidence ratios above 0.6 may be considered acceptable. When the match is not good, calibration terms can be introduced into the destination choice model to bring about a closer match. The calibration terms may help capture specific markets (e.g., central business district or CBD term) and entertainment districts, better replicate the proportion of intra-zonal trips (by including an intra-zonal variable or modifying intra-zonal travel times up or down for zones where issues exist), and improve the ability to match proportions within specific distance bands.

5. Mode Choice Models

Determining modal splits is often accomplished through the use of multinomial logit or nested logit models of mode choice. These discrete choice models are estimated on travel survey data sets, which are further augmented with transit on-board survey data because regular travel survey data may not include enough transit observations. Mode choice models should be calibrated by comparing against mode shares in a household travel survey data set. There is rarely an external data source that can provide population wide metrics of mode shares. Even if transit ridership counts are available, it is difficult to convert that to a true population mode share unless the total trips are well-established. If the activity-travel generation and destination choice steps are well calibrated, then it is potentially possible to derive transit mode shares and compare model predictions against observed mode shares. Recent availability of passive GPS/smartphone trace data and other location-based service (LBS) data also opens up opportunities for comparing model predicted vehicle trips against population level vehicle trips.

In general, however, most mode choice calibration and validation is done against household travel survey data for various market segments and trip purposes. The alternative specific constants are typically adjusted to better replicate observed mode shares; coefficients associated with explanatory variables should be adjusted only when absolutely necessary and in a behaviorally sound way. One robust way to check the validity of mode choice models is to use the coefficients on cost and travel time variables to compute values of time. These values of time can be checked against published literature to see if they are reasonable and consistent with expectations. Similarly, a ratio of coefficients associated with out-of-vehicle travel time (OVTT) and in-vehicle travel time (IVTT) can shed light on the relative penalty assigned to each of these travel time components. If the ratio is consistent with documented evidence and expectations, then the mode choice model may be appropriate for application. This ratio, for example, is expected to lie between 2.0 and 3.0. Essentially, computing elasticities, conducting mode choice specific sensitivity analysis, and evaluating trade-offs in attributes can serve as powerful mechanisms to validate mode choice models.

6. Time of Day Choice and Activity Scheduling/Timing Models

Travel demand models need to capture the temporal distribution of activity-travel engagement effectively to ensure that peak period travel estimates are accurate and policy decision-making to help relieve congestion is based on sound forecasts of time of day

distributions of travel demand. In traditional four-step travel demand models, simple time-of-day factors may be applied to split trip tables by time of day. Alternatively, time of day choice models may be estimated to compute the splitting proportions for each period of the day. Similarly, in activity-based travel demand models, time of day choice models are often implemented to determine timing and scheduling of activities and trips. In more continuous-time activity-based models (that do not split the day into discrete periods of the day, but rather simulate activities and trips along the continuous time axis while respecting time-space prism constraints), time of day is often an outcome of time use behavior and activity-travel duration decisions on the part of the agent.

Regardless of the exact methodology, the output of a travel model can be analyzed to construct distributions of activity and trip start times, end times, or midpoints. These distributions should be compared against time of day distributions in household travel survey data to determine whether the observed and predicted distributions match closely. The closeness of the match can be measured using chi-square test of the comparison of distributions or the coincidence ratio presented earlier. When the match is deemed less than acceptable, the time of day choice models or the activity and travel duration models can be re-calibrated to obtain a closer fit to the observed distribution. Typically, it should be possible to alter constants for different time periods of the day. In continuous duration models, intercept terms may be calibrated, or model specifications can be enriched to enhance fit. As a last resort, some fine tuning of model coefficients and parameters can be done through assertion. An important consideration is the ability of the model to respond appropriately, and reflect changes in activity-trip scheduling in response to changes in system conditions; for example, the model should be able to capture peak-spreading that may occur when peak period travel conditions (travel times) worsen.

7. Joint Activity-Travel Engagement and Vehicle Occupancy

There is considerable interest in representing intra-household interactions and inter-dependencies effectively in travel demand models. With emerging mobility services emphasizing sharing of vehicles, there is renewed interest in understanding ridesharing and car/van-pooling behaviors and the factors that could enhance shared mode usage. Vehicle occupancy has traditionally been captured in the mode choice modeling step, with explicit choice alternatives dedicated to auto travel with two passengers and 3+ passengers. In traditional travel demand models, the mode choice model captures shared/joint travel and the mode choice model calibration and validation procedures can be used to ensure the model replicates pooling effectively.

In more recent activity-based microsimulation models, joint tours are simulated with a view to represent household members traveling together, either to pursue an activity together or for chauffeuring passengers (e.g., drop-off/pick-up children at school). Household members may also travel separately, but meet at a location to pursue an activity jointly. Capturing these interactions is critical to representing coupling constraints in travel models. Once again, it is difficult to identify external sources of data that can be used to calibrate and validate joint tour engagement models (that generally take the form of discrete choice models or tour frequency/count models). The alternative specific constants and intercept terms would need to be adjusted to ensure a good fit with observed frequency distributions for different tour purposes. The household travel survey data is the best source of data for model calibration and validation; appropriate sensitivity tests can be performed to further verify model validity and reasonableness.

8. Highway Assignment Models

All travel models assign trip tables or trip chains to a model network comprised of links and nodes. Links are characterized by a number of attributes including length, speed, number of lanes, and facility and area type. Nodes may be characterized by turn penalties, intersection delays, and signal control information. Highway assignment results can be analyzed to obtain measures of vehicle miles of travel (VMT) by highway functional classification or facility type. In addition, most highway assignments will output traffic volumes on links by time of day and vehicle class. The traffic volumes can be used to compute link speeds and travel times, as well as origin-destination travel times. Comparisons are generally made against observed traffic counts, speed and travel time data available through detectors or a third party data source, and highway performance monitoring system (HPMS) data that is collected and reported by states on a regular basis.

A common method of validating highway assignment results involves comparing observed link traffic counts against model estimated values. This can be done for various link groups where groups can be defined by functional class, geographic market, area type, or traffic volume interval. For each group, the difference between observed and predicted link volumes can be measured using the Root Mean Square Error (RMSE) or %RMSE. Other measures of difference such as Mean Absolute Error (MAE) may also be used. The RMSE and %RMSE are formulated as follows:

$$RMSE = \sqrt{\frac{\sum_{i=1}^N [(Obs_i - Pred_i)^2]}{N}}$$

and

$$\%RMSE = \frac{RMSE}{\left(\sum_{i=1}^N Obs_i / N\right)} \times 100$$

where, Obs_i = observed traffic count on link i

$Pred_i$ = model predicted traffic volume on link i

N = number of links in group under consideration

Another useful measure of the fit between observed and modeled traffic counts is the coefficient of determination (R^2) associated with a scatterplot of observed versus modeled volumes. Scatterplots can be generated for different link groups; such scatterplots not only offer an ability to assess goodness-of-fit of the highway assignment results, but also provide the ability to identify outliers. Many jurisdictions have set criteria or benchmarks that should be met to consider highway assignment results acceptable (Cambridge Systematics Inc., 2010).

In general, the quality of assignment results depends on the ability of the model to accurately represent origin-destination flows in the region (by mode, vehicle class, and time of day) and the quality of the highway network. When poor validation results are obtained, the highway network should be checked for errors. In addition, comparisons of speeds and travel times should be conducted, preferably using third party data sources and detector (traffic management center or TMC) data. By comparing speeds and travel times, it will be possible to identify links and corridors where problems exist and make the necessary corrections. Finally, screenlines (that often represent natural boundaries across a region) or cutlines that cut across multiple facilities that comprise a corridor may be drawn, and the amount of traffic traversing these lines may be compared to ensure that the model is replicating traffic patterns appropriately. Checking volume-to-capacity (V/C) ratios is another useful exercise that can help identify network links where assignment results are not likely to be consistent with reality. Conducting extensive sensitivity analysis should be an element of any highway assignment validation exercise. The speeds or capacities of specific links and nodes should be altered and the change in assignment results for specific links (select link analysis) and the network as a whole should be assessed for reasonableness.

9. Transit Assignment Models

Transit assignment involves assigning transit trip tables by time of day and transit submode to the transit network. The path choice in the transit assignment process is often able to represent transfers involved in executing transit trips between origins and destinations. The path choice may also be used to capture choice between alternative transit submodes that may be serving the same origin-destination pairs, thus obviating the need to include all transit submodes as part of the mode choice model.

The validation of transit assignment results is usually done by comparing observed and model predicted stop-level boardings and alightings and route level ridership (by time of day period). As it may be difficult to replicate boardings and alightings at specific stops within various time periods, the comparisons of boardings and alightings may need to be done at a greater level of aggregation (groups of stops compared for broader time periods). Transit agencies generally have good route-level ridership data, and in many cases, stop-level automated passenger count (APC) data may also be available. In addition to these sources of data, many areas have comprehensive transit on-board survey data. On-board surveys conducted on a periodic basis can help provide much needed data for travel model estimation, calibration, and validation. The expanded and weighted on-board survey data can be used to construct transit trip tables against which model predicted transit trip tables can be compared for various time periods. Before any assignment exercise is conducted, it would be invaluable to ensure that the trip tables represent transit flows accurately.

The quality of transit assignment is highly dependent on getting the transit trip tables right, which requires the destination and mode choice modeling steps to provide accurate results. If the transit assignment results are not consistent with observed ridership counts and on-board survey data, then it would be advisable to revisit the mode choice step for sure and ensure that the transit mode shares and estimates are consistent with expectations and ground truth in the region. In addition, it would be advisable to check the accuracy of the transit network. One particular area that tends to be an approximation is the walk and auto access information associated with each zone. This aspect of travel models is recently gaining higher degrees of fidelity through the use of micro-analysis zones (MAZs) that are much smaller than TAZs. By using a finer zone resolution for transit access representation, it is possible to capture proportions of individuals with walk and auto access more accurately. Finally, any validation exercise should include a sensitivity analysis to see how ridership changes in response to fare, service frequency, and travel time changes. There is empirical evidence documenting how transit ridership changes in response to service changes, and this information can be used as the basis for assessing transit model validity (Evans, 2004).

Sensitivity Analysis of Model Components and Entire Model System

Sensitivity analysis is an important element of any model calibration and validation exercise. Depending on the reasonableness of the results of a sensitivity analysis, it is possible to loop back to any upstream steps in the model development process. It is possible to iterate back to the model specification and estimation step; the model form can be altered, specifications can be enhanced, and coefficients can be re-estimated or re-asserted. It is possible to iterate back to the model calibration step where the model form and specification are retained, but coefficients and parameters are adjusted to offer a level of sensitivity that is more in line with expectations and any available empirical evidence.

Quite often, the terms sensitivity analysis and scenario analysis are used rather interchangeably. For most practical purposes, that is indeed appropriate; by applying the model to a set of alternative scenarios, it will be possible to assess the sensitivity of the model to changes in input conditions. Sometimes, however, a sensitivity analysis refers to an elasticity or marginal effect computation, i.e., the change in dependent variable or choice probability in response to a unit change in an independent variable. Marginal effects and elasticity values serve as measures of sensitivity. When the scenario involves a change in input variable(s) that has a cascading influence through a series of model components, then the sensitivity analysis may be more appropriately badged as a scenario analysis to clearly indicate that the model outputs reflect changes in travel demand captured by the model system as a whole.

Table 1 Scenario descriptions for model sensitivity analysis

Scenario	Description	Changes to base year
Base scenario	2003 is the analysis year	—
25% increase in population and employment densities	Population and employment in the study area are increased by 25%	Population and employment density measures were increased by 25%
100% increase in cost—drive alone mode	A 100% increase in cost for drive-alone for all time periods	Cost tables were altered by multiplying the drive alone auto cost by two in the AM, PM, and off-peak files
25% increase in IVTT— auto mode for all periods	A 25% increase in IVTT for the drive alone and shared ride for all time periods	IVTT tables were altered by multiplying the auto IVTT by 1.25 in all time periods
25% increase in IVTT— auto mode and peak periods	A 25% increase in IVTT for the drive alone and shared ride for the AM and PM peak time periods	IVTT tables were altered by multiplying the auto IVTT by 1.25 in the AM and PM peak files

Scenarios should be constructed such that the outputs can be assessed for their reasonableness and potential accuracy (through comparisons with available empirical evidence). In some cases, however, it may be useful to check extreme (potentially unrealistic) scenarios so that the limits of the model system are tested and the analyst can determine the boundary conditions within which the model is able to offer plausible and defensible forecasts. In the context of future transportation technologies, this becomes more involved as there is considerable uncertainty on how these technologies will evolve and find their way into the transportation marketplace.

An illustration of a scenario analysis is furnished in this section, in the context of a first-generation activity-based microsimulation model of travel demand developed and applied for the Southern California region several years ago (Goulias et al., 2011). The initial model development effort involved synthesizing and simulating the activity-travel patterns of about 18 million people in just over 4000 traffic analysis zones (TAZs). Following the model development process, there was a desire to determine how systemwide changes in cost and travel time would impact those below and above the poverty line. Activity-based microsimulation models facilitate comparisons across socio-economic and demographic groups, thus enabling equity analysis of alternative transportation policies.

Table 1 presents the system-wide scenarios that were tested using the model. The base year was 2003, and the scenarios essentially constituted a 25% increase in population and employment densities, a doubling in the cost of drive alone mode, a 25% increase in in-vehicle travel time (IVTT) for the auto mode in all time periods of the day, and a 25% increase in IVTT for the auto mode during peak periods. These scenarios were applied in isolation (not as a combination of changes). After applying the model system, changes are predicted in all aspects of activity-travel patterns. Activity-trip frequencies, destination locations, and mode choices change; scheduling and chaining of activities and trips is altered; and joint activity-travel engagement with other members of the household is altered as well.

In the interest of brevity, illustrative results are presented for an aggregate and a disaggregate sensitivity analysis. **Table 2** presents the changes in average trip lengths for different trip types. The three trip types are home-based work (HBW), home-based other (HBO), and non home-based (NHB). In all cases, it is expected that average trip lengths will decrease. An increase in cost or time (impedance measures or travel skims) will have the effect of reducing trip lengths. Similarly, an increase in employment and population density will also engender a shift towards shorter trips. It can be seen that the results in **Table 2** are consistent with these expectations and reflect shifts in trip lengths that are behaviorally intuitive. In general, work trips are largely inflexible and as a consequence, the trip lengths for HBW show the smallest percent change. On the other hand, HBO trips exhibit the greatest level of change in trip lengths, consistent with the notion that these are mostly personal business, social-recreational, and shopping trips.

Table 2 Changes in average trip lengths by trip type and poverty group

Trip type	Base case Avg (mi)	DA cost increase 100% Avg (mi)	% Reduction	DA IVTT increase 25% Avg (mi)	% Reduction	Peak period DA IVTT increase 25% Avg (mi)	% Reduction	25% Increase in empl & pop densities Avg (mi)	% Reduction
Below poverty									
HBW	11.17	10.21	8.6%	10.68	4.3%	10.67	4.5%	10.70	4.2%
HBO	10.52	6.91	34.3%	5.48	47.9%	6.37	39.5%	6.95	33.9%
NHB	7.49	7.06	5.8%	5.74	23.3%	6.58	12.2%	7.12	5.0%
Total	9.69	7.28	24.9%	6.11	37.0%	6.87	29.1%	7.40	23.7%
Above poverty									
HBW	11.19	10.53	5.9%	10.95	2.1%	10.92	2.5%	10.99	1.8%
HBO	10.15	8.37	17.5%	6.72	33.8%	7.77	23.5%	8.42	17.1%
NHB	7.99	7.71	3.5%	6.36	20.4%	7.27	8.9%	7.84	1.9%
Total	9.68	8.52	11.9%	7.39	23.6%	8.16	15.7%	8.72	9.9%

Note: DA, drive alone; HBW, home-based work; HBO, home-based other; IVTT, in-vehicle travel time; NHB, non home-based

Table 3 Illustration of impact of drive alone cost increase on activity-travel pattern of an individual

<i>Base case</i>		
Overall pattern		Commute and additional tour
Total miles		47.17
	Home → Work commute	
Number of non-work stops		0
Mode		Drive alone
Activity at non-work stops		—
	Work → Home commute	
Number of non-work stops		0
Mode		Drive alone
Activity at non-work stops		—
	Tour 1	
Number of stops		1
Mode		Drive alone
Activity at stops		Eat out
<i>Policy case (Doubling of drive alone cost)</i>		
Overall pattern		Commute tour
Total miles		35.21
	Home → Work commute	
Number of non-work stops		0
Mode		Drive alone
Activity at non-work stops		—
	Work → Home commute	
Number of non-work stops		1
Mode		Drive alone
Activity at non-work stops		Eat out

Finally, NHB trips show rather modest changes in trip lengths as well; these are likely to be work-based trips (say, during the lunch hour) or intermediate trips within a longer trip chain. Indeed, the percent change is smaller than that for HBO trips and more than that for HBW trips (except for the case where drive alone cost doubles). Since these trips are relatively shorter to begin with, it is reasonable to find that NHB trip lengths show lower sensitivity to cost than to travel time. In all instances, the percent change is larger for the “below poverty” market segment when compared with the “above poverty” market segment. This is behaviorally intuitive as one would expect those below the poverty line to be more adversely impacted and sensitive to changes in impedance (cost and travel time).

Finally, **Table 3** presents an illustration of the change in activity-travel behavior for an individual agent in the population, thus representing a very disaggregate validation exercise. By examining individuals in the synthetic population, it is possible to see how their activity-travel patterns changed from one scenario to another. This Table shows what happens to an individual when the drive alone cost doubles.

It is found that a doubling of the cost results in the individual adopting a more efficient activity-travel pattern. In the base case, the individual undertakes a commute tour (Home→Work→Home) with no intermediate stops on either journey to or from work. The individual undertakes a separate home-based tour to eat out, resulting in a total distance traveled of 47 miles. In the policy case, when drive alone costs are doubled, the individual makes a stop to eat out on the way back home from work, presumably gaining efficiencies in distance (and hence cost). This modification of the activity-travel pattern results in the individual traveling only 35 miles in the policy case. This change in mileage and the change in activity-travel pattern are behaviorally intuitive, suggesting that the model is able to predict changes in travel demand in response to changes in system conditions without necessarily violating basic rules and constraints. The decrease in mileage (of about 12 miles) may be checked against historical evidence of how person or vehicle miles of travel have changed in response to changes in driving cost. In general, it is known that travel mileage is quite insensitive to driving costs (Brons et al., 2008), and so a change of this magnitude can only be realized with a dramatic increase (doubling) in travel cost.

Summary

Model calibration and validation is a very critical step in the model development process. Unless a model has been appropriately calibrated and verified to be “valid,” capable of providing reasonable and useful forecasts for transportation planning and policy making, it should not be adopted. To the extent possible, model validation should be done at a fine-grained level, checking model

outputs separately for various market segments, geographic subareas, network corridors and links, and times of day. In this way, it is possible to ensure that the model is capable of reflecting the heterogeneity that often characterizes activity-travel demand in a region.

Given the importance of these steps, it is critical that enough resources and time be dedicated to these tasks in the model development process. Quite often, resources and time are spent developing the model specification and estimating models, leaving very little to go through extensive calibration and validation exercises. Recognizing that calibration and validation is at least as important, if not more than, model estimation is critical to ensuring that appropriate resources and time are allocated to these efforts. Calibration and validation should be done for each model component and for the model system as a whole. Validation data should be assembled with care and checked extensively for accuracy to ensure their appropriateness as a basis to assess model performance.

Finally, model calibration and validation exercises should be fully documented. Documentation of these efforts can help model users understand how the models came to be specified and structured the way they are, how the models are expected to respond to changes in input variables, and appropriate limits beyond which model capabilities may be stretched in ways that are not fully valid or adequately tested. The model calibration and validation documentation should present scenarios tested, predictions obtained, and an assessment of the reasonableness and potential value of the forecasts. Metrics used to assess validity should be documented for each model component and the model as a whole. Care should be exercised when applying models to new and emerging transportation and mobility scenarios featuring technologies and services that do not currently exist anywhere in the real-world. Given the large degree of uncertainty as to how emerging transportation technologies and shared mobility services may evolve in the years ahead, forecasts are heavily dependent on underlying assumptions of technology capabilities and features and market behaviors. Thus, any and all forecasts should be accompanied with clear documentation of underlying assumptions so that decision-makers can assess the validity and usefulness of the model outputs.

An exercise that the profession should increasingly adopt as part of standard model calibration and validation efforts is that of backcasting or forecasting from the base year to the current year. The base year is often a year that is a few years in the past (when compared to the year in which the model development is completed). By applying the model to forecast to the present year, it will be possible to assess the ability of the model to replicate ground truth conditions. Similarly, the model can be applied to backcast to a past year by using the socio-economic and network inputs of the past year. Because ground truth conditions are known for the prior year, it will be possible to assess the ability of the model to replicate real-world traffic patterns when absolutely correct inputs are fed into the model (any error must be largely due to model specification errors). Although time intensive, exercises that involve backcasting and forecasting can prove invaluable in determining validity of travel models and identifying model components that need to be re-calibrated to better replicate real-world conditions.

Definition

A trip is simply travel from one place to another by any means of travel. A trip chain is a series of trips chained together. Although there is no formal definition on the definition of a trip chain, there are common terms and expectations to describe whether a series of trips should be considered part of a chain (Primerano et al., 2008). In many cases, a trip chain comprises a series of trip that start and end at one's anchor locations, which may or may not be same. An anchor location is one that is not only regularly visited but also is a key (anchor) point for other trips conducted in a day. Home and work places are typically considered as one's anchor locations because other trips are often made around them. A related concept is tour, which is also defined as a series of trips chained together. The key difference between a trip chain and a tour is that the former is a general reference to a series of trips chained together and the latter is a specific reference for trip chains that start and end at the same anchor location. Common tours are home-based or work-based tours, referring to a series of trips that start and end at home or work, respectively.

Fig. 1 illustrates the differences between trip, trip chaining, and tour. In this example, the individual drives from home in the morning to a Park and Ride location, parks her car, gets on a bus and arrives at work. At noon, she walks to a restaurant for lunch and then walks back to office. In the afternoon, she carpool with colleagues to another restaurant for dinner. Afterwards, her colleague drops her off at the Park and Ride location where she picks up her own car and drives home. Here, there are five separate trips: home to work, work to lunch, back to work from lunch, work to restaurant, and restaurant to home. There are two tours: one home-based tour capturing the entire daily mobility pattern from home in the morning and then back home in the evening and the other work-based tour for two trips at noon: from work to lunch and then back to work. Both of these tours can also be viewed as trip chains with the same origin and destination. Additionally, there are two other trip chains: the first is from home to Park and Ride location and then to work in the morning and the second one is from work to restaurant for dinner and then back home in the evening. In both cases, the start and end points are different and both also involve a stop in a middle.

From Trips to Trip Chains

It is a landmark recognition in the travel behavior research (an area that studies how individuals make travel-related decisions such as mode choices, route choices, and departure time choices, etc.) that trips shall not be studied independently but together (Adler and Ben-Akiva, 1979; Kitamura, 1984). This recognition is a stark departure from decades' running four-step models that has treated trips independently. The key reason for this shift is the recognition of history and future dependence between trips. The fact that the car is parked at a Park and Ride location prevents one from driving to the restaurant for dinner in the evening (history dependence) and the expectation that driving to and parking at the restaurant in downtown in the evening makes one decide to drive to a Park and Ride location and take the bus to work in the morning (future dependence).

Trip Chaining in Relation to Congestion, Emissions, and Public Health

Transportation researchers have longed recognized the role that trip chaining plays in societal phenomena that affect everyone's welfare, such as congestion, emissions, and public health. The overwhelming reliance on automobiles in the United States is viewed

Figure 1 A 3D illustration of one individual's mobility pattern in a day.

as a significant cause behind widespread and increasing congestion in many metropolitan regions, declining transit ridership, CO₂ emissions, and prevalence of obesity. Automobiles still surpass other modes in its ability of chaining trips to accomplish desired activities that are often distributed in space. In other words, while reducing America's reliance on automobiles represents potentially the most effective strategy in reducing congestion and CO₂ emissions and improving public health, it is also the most difficult one. There are significant barriers in the use of alternative modes (other than autos) in completing the trip chains. Take the example of transit use: the most critical barrier relates to the first and the last mile of a trip'the difficulty in accessing a transit station from an origin and reaching a destination from a transit station prevents many from using transit.

The Decision Theory and Models Explaining Trip Chaining

The dominant decision theory underlying trip chaining is random utility maximization, where an individual is assumed to be a rational decision maker. When faced with a set of alternatives, she is to evaluate and trade-off between the various decision factors and select one that maximizes her satisfaction (utility). Since trips are primarily made to conduct activities at the destinations, the utilities are expressed in negative terms and the goal is then to minimize one's disutility.

The classic model based on random utility maximization for explaining trip chaining is the discrete choice model where each alternative is discrete and finite and the decision maker is said to choose the one that maximizes her utility (Ben-Akiva and Lerman, 1985). Each alternative has a utility function that explains how different factors may come together to approximate the amount of (dis)satisfaction that may incur if that alternative is chosen. Inherent in the utility function is the trade-off nature of the decision-making process, meaning that one unattractive feature, for example, long travel time, can be compensated by an attractive feature, for example, being inexpensive. Because of this, the utility function is often expressed as a weighted sum of various factors, with the weights being the decision maker's preferences, or values toward different factors.

Because more than one decision is involved in a trip chain, complex discrete choice models have been developed. There have been two modeling approaches: simultaneous (Bowman and Ben-Akiva, 2001) vs. sequential (Kitamura et al., 2000). The simultaneous approach assumes that prior to the start of a trip chain, one develops a few alternatives regarding its general pattern composition, for example, a trip chain with one stop or two stops. The individual will first decide on which pattern is to be adopted, followed by decisions that need to be made within a particular pattern. For example, one may first select a trip chain with one stop, and then proceed to decide on the mode choices to and from the stop within the chain. In modeling, the simultaneous approach is often formulated as a hierarchical model with multiple decisions involved and the estimation of these multiple decisions is

simultaneous. The sequential approach assumes that individuals are myopic and do not first develop a general idea of how a trip chain may be conducted. Instead, decisions are made in a sequential way, one trip chained after another. In modeling, the sequential approach is often formulated by a sequence of discrete choice models, conditioned one after another.

Factors Affecting Trip Chaining

Three categories of factors have been consistently identified to affect trip making: structural (alternative related) factors, the built environment, and socio-demographic attributes. Structural factors directly affect the (un)attractiveness of an alternative. The most common structural factors are travel time and travel cost. There are also alternative-specific factors that only matter to certain alternatives, for example, parking availability and cost associated with driving; waiting time, number of transfers and distance to transit associated with transit; availability of sidewalk for walking; and elevation for biking. The structural factors have long been considered as most important factors explaining trip making behaviors, given that individuals are rational decision makers. Though many behavioral nuances have been found to suggest many irrational aspects in individuals' decision-making processes, the assumption that in trip making, individuals are mostly rational is still considered valid.

The built environment determines the availability of options and their levels of accessibility for trip making. For example, if there is not a transit stop within a close range (e.g., 0.5 mile), transit cannot be considered a viable option. In the context of trip chaining, the availability and accessibility of a particular mode choice (e.g., transit) for any part of a trip chain could be a deciding factor for selecting a mode for the entire trip chain. Temporally, the availability of an opportunity at a destination can both dictate the departure times associated with the trips in a chain and the mode choices used. The opportunity and accessibility effects afforded by the built environment have been measured with metrics in five D categories (Ewing and Cervero, 2010): density, diversity, design, destination accessibility, and distance to transit. These effects are not uniform across all: for example, research has found that the built environment affects the travel behavior of men and women differently.

Socio-demographic factors include both one's personal attributes (e.g., age, gender, and physical disability) and demographic characteristics (e.g., being a part of a household, a neighborhood, a company, or a community). These factors often shape one's responsibilities and constraints at work, in families, and in society. They also reflect long-standing traditions, culture, and practices in a society. As an example, the obligation to pick up children prevents one from taking transit and dictates her to depart from work by a certain time. These factors (personal and social) are often intertwined together. Women are found to have more complex trip chaining patterns in both time and space due to their continuing primary care responsibilities in the household, despite a significant rise in women's participation in the workforce (Hanson, 2010; Kwan, 1999). Interestingly, women's higher shares of family obligations are often coupled with their lower mobility levels, as reflected in fewer access to vehicles and drivers' licenses. Previous studies (Susilo et al., 2019) show that low mobility levels and time-space constraints, such as childcare obligation, are two key factors explaining why women tend to work closer to home and use more public transport, compared with their male counterparts.

These three categories of factors can also be understood in Hägerstrand's space-time prism framework (Hägerstrand, 1970), which illustrates various elements in a trip chain in a 3D time-space comprising a vertical time dimension and a two-dimensional physical space (see Fig. 1). The constraints one faces in completing the trip chaining are of three kinds: (1) capacity constraints due to our biological limits (e.g., one must allocate time for eating and sleeping) and physical constraints (e.g., one cannot run faster than a vehicle); (2) coupling constraints that arise from limits in one's resources (e.g., lack of a car) or from the built environment (e.g., lack of public transportation nearby); and (3) authority constraints due to rules in a society (e.g., one shall not drive faster than the speed limit or stores are not open at night).

Aside from the above three categories of factors, there are other factors that affect trip chaining. Weather, for example, has been found an important factor in use of nonmotorized modes such as walking and biking: cold and rain are severe barriers for biking and walking. Attitudinal factors are also found to be important: their roles in affecting trip making behaviors are complex (Wang and Chen, 2012)—interacting with other factors, as latent factors forming a hierarchical decision structure, and acting as nonlinear thresholds that could distort the trade-off nature assumed in the classic random utility theory.

Additionally, there is increasing recognition that factors that often suggest behavioral irrationality can also play a role in explaining trip making behavior. This is where a number of other prominent behavioral and social and psychological theories coming into play. Examples include prospect theory (Kahneman and Tversky, 1979) and peer influence. Prospect theory identifies three aspects in explaining behavior: (1) framing effect: a scenario stated positively vs. negatively results in different behavioral choices; (2) risk seeking vs. avoidance: risk seeking is associated with loss and risk avoidance is with gain; and (3) when faced with uncertain scenarios, people attribute excessive weights to low probability events and insufficient weights to high-probability events. Peer influence refers to the decisions made to conform with those made by peers, even though the choice itself may derive lower utility for the decision maker. In a modern society characterized by ubiquitous access to the internet (and thus information) and prevalence of mobile devices, it is expected that these factors will play an increasingly important role in trip making behaviors.

It is important to note that all factors including the trip chaining behaviors evolve over time and this is due to changes at all levels, individual, family, community, and society. For example, recent studies (Susilo et al., 2019) have shown that older generations of partnered/married young women have fewer trips per work trip chain than their male counterparts, but this gender difference is becoming smaller among younger generations. The declining gender difference is mainly due to changes in gender effects in the number of trips and activity duration through indirect effects. The women from younger generations, including those who have children, are becoming more active in out-of-home non-work activities and having more complex trip chaining, compared to their male counterparts.

Trip Chaining, Transit Use, and Emerging Mobility

As noted earlier, trip chaining plays a critical role in transit use: significantly increasing transit use requires solving the first and last mile problem in trip chaining. In the past, access to transit is limited to those who live within a short distance (e.g., 0.5 mile) to the station and those who do not live within walking distance to a transit station but can drive and park near a station. In the United States, the former are largely in a few densely populated urban areas and the latter are primarily in suburban area whose primary use of transit is for commuting purposes. Together, these two populations account for a small percentage in the nation, resulting in a low share of transit use in most of the metropolitan areas except a few large cities (e.g., New York City and San Francisco).

The rise of emerging mobility services such as Uber and Lyft has aroused new worries and hope for transit use and both are related to trip chaining. The nearly ubiquitous presence of those new services in urban areas has prompted multiple studies that seek to answer related questions such as “whether the new mobility services are generating new trips, and/or attracting trips from solo-driving (which is encouraging) or from transit (which is discouraging)?” and “to what extent do these new mobility services contribute to congestion?” Today there seems to be substantial evidence from multiple studies in different locales pointing to the contribution of the new mobility services to congestion as well as their role in attracting transit users and thus declining transit ridership.

There is also new hope that the emerging mobility services may potentially boost transit ridership by providing an efficient and cost-effective means for the first- and the last-mile. Recent years have seen a number of cities (e.g., NYC, Seattle, San Diego, DC, and LA, etc.) that have or are experimenting with using new mobility services to solve the first- and last-mile problem (Marshall, 2019). The various types of experiments include, for example, providing free or discounted rides for economically disadvantaged riders or those within certain geographic areas, providing discounts (absolute \$ amount or in percentage terms) for rides to/from certain stations or for particular corridors, and integration of Uber/Lyft services in transit mobile apps. Some agencies (e.g., Livermore-Amador Valley transit and Arlington County) even experimented with replacing the traditional dial-a-ride and certain low-demand fixed-route services with new mobility services. Since this is a very recent phenomenon, there have not been conclusive results pointing in either direction. Some very early experiments (e.g., Kansas City, Missouri and Centennial, Colorado) recently ended after disappointing results, but they may be attributed to reasons such as lack of marketing effort for raising the awareness.

Trip Chaining Analysis in an Era of Big Data

Analysis of trip chaining gained its prominence after the landmark recognition of its important role in travel behavior analysis. Today, activity-based models in place of the traditional four-step models for travel demand forecasting directly recognize the importance of trip chaining and build individuals' daily mobility patterns as a series of trips chained together. These models are typically built based on household travel survey data, which contains information on all trips conducted during 24 h for a small but representative sample of a region's population. In the household travel survey data, how a series of trips are chained together within 24 h is directly observed through either self-reporting or a combination of active GPS logging at regular intervals (e.g., every 10 s) and confirmation by survey participants.

The last 10 years have also witnessed a surge of studies using passively generated, big data (e.g., phone data, app-based data, social media data) for deriving individuals' mobility patterns (Chen et al., 2016). Passively generated, because such data is generated as a by-product of attaining primary purposes such as billing, operation, and maintenance. Trips and how a series of trips are chained together cannot be directly observed from such data; they can only be inferred. It is thus apparent to see that since the data is not generated to capture one's trip making behavior throughout a day like the household travel survey does, it is possible or quite likely that certain trips within a chain will be missed. In fact, under-estimation of trips has been observed in a number of studies using such data. It is however also worthy to note that the emphasis of trip chaining seems to have diminished in studies using big, passively generated data to derive mobility patterns. This is reflected in three aspects: (1) trips are the dominant unit of interest in vast majority of the studies as opposed to trip chains; (2) little understanding of what types of trips tend to be missed in trip chains and how they affect our ability in deriving mobility patterns; and (3) there is also little work that attempts to recover missed trips by leveraging the history and future dependences between trips in a chain.

Concluding Thoughts

It is the trip chains (a series of interdependent trips chained together), not independent trips, that underlie our daily mobility patterns. Therefore, studies on individuals' trip making behavior or mobility patterns shall recognize the linkages between trips. This notion is important in all inquiries, whether it is to understanding individuals' travel behaviors, predicting them, or seeking to change them. It shall also remain important no matter what type of data is used, actively generated data such as household travel surveys or passively generated big data (e.g., phone data, app-based data, or social media data).

As noted earlier, individuals' trip chaining behaviors directly contribute positively or negatively to several phenomena of interest at the society level, such as congestion, emissions, and obesity. The ability to trip chain transit trips with other modes together will potentially boost transit ridership, reduce emissions, and obesity (by increasing physically active travels); on the other hand, the inability to chain transit trips with other modes loses ground to automobiles, thus directly adding to congestion, emissions and public health crisis including obesity. From this perspective, how to help individuals achieve effective and sustainable trip chaining

may be an important opening for potential behavioral changes. Recent studies (Duncan, 2016) have shown that trip chains (in particular, work-based tours) have the potential of reducing VMT by 20%–50%, when compared to multiple trips with separate destinations. This suggests that offering recommendations to people on how to schedule and reschedule their trips together may be a viable option for sustainability purposes.

Acknowledgments

Funding for this research is provided by a NSF (National Science Foundation) grant (CMMI 1536340) and a NIH (National Institute of Health) grant (1R01GM108731-01A1) to Cynthia Chen. The authors thank the help of Feilong Wang, a PhD student in the Department of Civil and Environmental Engineering, University of Washington (Seattle), for his help in creating the figure.

Biographies

Cynthia Chen is a professor in the Department of Civil and Environmental Engineering at the University of Washington, Seattle. She received her doctoral degree from University of California, Davis. Her main research interests are understanding human mobility patterns with big and small data, cascading processes on networks, and intervention designs for behavioral modification.

Yusak Susilo is a BMVIT Endowed Professor in Digitalisation and Automation in Transport and Mobility Systems at the University of Natural Resources and Life Sciences (BOKU), Vienna, Austria. He received his doctoral degree from Kyoto University, Japan. His main research interest lies in the intersection between transport and urban planning, transport policy, decision-making processes, and behavioral interactions modeling.

Introduction

Vehicle ownership represents a material precondition for transport-related participation in society. In this sense, vehicle ownership both enables and restricts the realization of spatially differentiated activities. With regard to the individual subject, vehicle ownership has a high behavioral relevance, which is often described as a commitment between vehicle ownership and use (Simma and Axhausen, 2003). The decision for specific vehicle ownership has long-term and short-term consequences with regard to individual travel behaviors. The long-term nature of the consequences is reflected, for example, in certain Modality Styles, that is, behavioral predispositions characterized by a certain mode or set of modes that an individual habitually uses and which are expressed in long-term anticipated spatial activity patterns of the traveler. For example, (monomodal) car users organize their locations and all associated distances around their home, workplace, leisure activities, etc. from behind the steering wheel of their car. The short-term consequences of owning a vehicle are equally effective in the situational moments of everyday activities, that is, spontaneous or planned activities including frequency, duration, geographical location, etc.

Over the past decades, a complex and heterogeneous variety of vehicle ownership models has developed that can be used. Many model approaches are unknown, for example, due to the fact that the private sector generally operates within the framework of trade secrets. Vehicle ownership models are used for different purposes in all sectoral areas (politics, business, science, nongovernmental organizations, etc.). What all these approaches have in common is that they seek to explain and/or understand vehicle ownership in some way, in order to draw appropriate conclusions. Governments and administrations at the political-administrative level, for example, use vehicle ownership models to simulate traffic demands, calculate tax revenues, or also estimate climate-impacting emissions and draw up action plans. The manufacturers of specific transport modes from the private sector in turn use vehicle ownership models to predict the demand for specific vehicle types — for example, for specific car brands or bicycle types — and thereby, profit expectations. For transport and mobility research, the focus is on concrete epistemological approaches to understanding and explaining ownership patterns and the associated consequences.

Many methodologically sophisticated vehicle ownership models can be located in the context of the global north. Since these countries are largely characterized by automobile societies, modeling often occurs according to car ownership. With the growing questioning of the automobile, however, a number of other focal points have emerged in recent years, such as the trends toward multimodality or new transport systems. Therefore, the terminology used differs across studies with regard to different questions and the interdisciplinary composition of the actors. For example, in addition to vehicle ownership, other terms too, such as “mobility resource holdings” (Le Vine et al., 2013) or “mobility tool ownership” (Scott and Axhausen, 2006) are used.

Aggregated Vehicle Ownership Models

The different vehicle ownership models are distinguished according to aggregated and disaggregated approaches. Aggregated models are based in different ways on general social structural data for modeling vehicle ownership. The application of aggregated vehicle ownership models has a very long tradition, often based on general demographic or economic parameters. An example that has attracted much attention beyond the boundaries of transport and mobility research are the “patterns of automobile dependence in cities” in various regions of the world, identified by Kenworthy and Laube (1999), in which they use the GDP (and also density factors) to explain car ownership. Due to their limited data quality, such aggregated models are particularly suitable for simple analyses. A typology of aggregated model types is provided by de Jong et al. (2004), *inter alia*, by comparing studies of different car ownership models to which belong aggregate cohort models and aggregate time series models.

Cohort models make use of aggregated demographic data on vehicle ownership. Here, the population is divided into certain age groups [e.g., according to (1) minors up to 17 years, (2) young adults from 18 to 27, (3) adults between 28 and 49, (4) older adults between 50 and 65, etc.]. A common goal of grouping the population by age is to extrapolate future trends in ownership structures using scenario techniques. In the 1980s and 1990s, for example, cohort models were used in countries of the global north to forecast rising motorization rates for the future (Jansson 1989). This assumption was derived from the analyses as follows: the older generations born before the Second World War grew up at a time when car-owning lifestyles were not yet established. At the time of the survey, this age cohort had significantly lower motorization rates than the younger generations of the subsequent car era. On this basis, it was assumed that the degree of motorization would increase ubiquitously with future generations. However, current studies on Generation Y indicate that in most countries of the global North, motorization of societies in this Generation Y will be curbed by a significant decrease in car ownership and driving license rates (Delbosc and Currie, 2013). It is not yet clear how stable this shift away from tools for car use is. In political planning practice, this development is seen as crucial for promoting alternatives to the private car even more strongly than before and thus promoting sustainable development trends for the transport sector.

In time series models, aggregated economic data on the ownership of transport modes are commonly used. In many cases, saturation processes are illustrated using the sigmoid function and various special cases such as the Gompertz curve. As explanatory variables for specific vehicle ownership in societies, the time series models use, for example, GDP, buying power data, oil prices, population densities, etc. These models are based on economic assumptions of diffusion theory and analyze diffusion processes of ownership. The tendency toward low data requirements makes it possible, for example, to model specific vehicle ownership structures in one or more countries, in order to examine and problematize the unequal degree of motorization of regions in the global south and global north with regard to economic parameters. Particularly noteworthy are the works of Dargay and Gately (1999) and Dargay et al. (2007), who use an econometrically estimated model to forecast the growth of the automobile and vehicle population in countries of the global north and the global south, taking into account short- and long-term income elasticities. The studies have a high impact, because they assume that the global vehicle inventory will grow from around 800 million in 2002 to more than 2 billion in 2030. These forecasts raise political questions about the extent to which the expansive demand for oil can be met.

Disaggregated Vehicle Ownership Models

Disaggregated models aim to understand transport ownership more precisely and in more detail, starting from the individual or household level, than would be possible with aggregated models. In recent decades, an extensive and complex variety of disaggregated vehicle models has been developed that differs in terms of (1) theoretical-conceptually deposited explanatory variables, (2) methodological approaches, and (3) political implications. Due to the increasing number of scientific publications, meta-analyses of published data and systematic literature reviews on vehicle ownership models and their effects on behavior and transport systems already exist. The literature review by Anowar et al. (2014), which initially roughly differentiates between exogenous and endogenous models, deserves special mention: exogenous models treat vehicle ownership as being independent of other decisions. Endogenous models, on the other hand, include other decision-making processes for vehicle ownership, in addition to subjective decision processes for specific vehicle ownership. This is based on the assumption that vehicle ownership can by no means be treated only as an exogenous factor for vehicle use, for example, but depends on various decision-making processes (e.g., positive emotions toward a vehicle or a specifically pronounced awareness of environmental problems).

The application of exogenous vehicle ownership models or endogenous vehicle ownership models is suitable for answering very different questions. Exogenous models may be used, for example, to model greenhouse gas emissions in terms of available fleet composition by car type. Methodologically, classical forms of discrete decision experiments are often applied. In many works of the last few decades, especially logistic regressions based on disordered mechanisms have been established in order to prove the behavioral relevance of vehicle ownership. Endogenous vehicle ownership models, in turn, aim to better understand the complex interrelationships for vehicle ownership decisions of the individual or the household. Beyond all used consideration, structural equation models have proven their worth in uncovering more complex relationships. They are usually based on two components: (1) a preceding factor analysis with which correlating background variables are combined into factors and (2) the structural equation with which the directional relationships of the factors and observed variables are checked. The direct, indirect, and total relationships of the explanatory variables are made visible in order to explain the corresponding effects on the specific mode of vehicle ownership and use.

In understanding changes in vehicle ownership based on the individual and/or the household, time plays an important role in the models. Models can be static or dynamic. Static vehicle ownership models examine vehicle ownership at a certain point in time, usually based on crosssectional data, taking explanatory variables into account. They represent a kind of snapshot in time. Dynamic vehicle ownership models, on the other hand, examine vehicle ownership taking into account dynamics over time. They assume that vehicle ownership is by no means static. For this purpose, researchers usually draw on panel data sets based on longitudinal surveys. Pseudo panels can also be used, in which crosssectional surveys were carried out at different points in time. Methodologically, in the crosssection of many studies, different methods are used to model vehicle ownership. The approaches range from mixed multidimensional choice modeling techniques, discrete continuous models, copula-based models and Bayesian models, to simultaneous equation models and structural equation models.

Finally, in the disaggregated modeling of vehicle ownership, objective and subjective factors are used to explain ownership patterns (van Acker et al., 2011). Behind this lie specific theoretical-conceptual assumptions, according to which ownership structures are to be explained on the basis of objective determinants (e.g., life situations) or subjective determinants such as mode-related psychologies. The fact that the objective and subjective factors cannot always be easily separated can be illustrated by the example of the built environment, which structurally foresees specific types of transport use, but which is also reproduced by specific individual preferences for neighborhoods and related transport modes.

Objective Factors: The Example of Life Stages

The concept of life stages plays an implicit role in disaggregated models of vehicle ownership. In the social sciences, life stages represent the interaction of social roles, available resources, and corresponding restrictions. This is based on the theoretical assumption that in the course of their lives people find objective/external living conditions that should be understood against a cultural background and which are determinants of expected decisions (e.g., vehicle ownership decisions): For example, while working people drive to work and need a car, students go to university and own a “semesterticket”/a student public transport pass, the poor have no money and therefore only have inexpensive transport modes available and so on.

In vehicle ownership modeling, life stages are often simplified and translated into sociodemographic or socioeconomic variables, which are intended to explain vehicle ownership, for example, with regard to fleet sizes, vehicle types or different modes including mode usage. Explanatory variables for vehicle ownership are, for example, occupational position, income, age group, family status, or sex. In addition to such sociodemographic and socioeconomic variables, variables on land use or infrastructural accessibility indicators (e.g., distance to the nearest train station) are also used (not always without contradiction).

In the course of time, it is shown that vehicle ownership changes with specific life events such as the birth of a baby, the transition into working life or when moving. One example is the multimodal tool ownership of young adults in Generation Y, which is increasingly associated with life situations beyond car captivity: compared to earlier generations of young adults, Generation Y is more often located in cities with good accessibility structures, studies more frequently at universities, is not at work, and lives more frequently in single households than in family households. With regard to the dynamic ownership models, however, there is concern that a later entry into employment and/or a delayed family formation could lead to the postulation of the necessity of owning cars, which in turn will trigger car use patterns (Article 10429: Young Adults’ Travel: Patterns and Evolution).

Such observations on life stages are important for political implications, because they also provide information about the key events in which a “window of opportunity” opens for the purchase of a new transport mode and possible behavioral changes (Article 10423: Mode Choice and Life Events). For example, if policymakers want to counter the imminent car purchase by young future parents, they could explicitly address parents through political initiatives and offer them attractive alternatives to private cars (e.g., family cabins or discounted family tickets for public transportation).

Subjective Factors: The Example of Mode-Related Psychologies

More recent disaggregated models are increasingly integrating psychological perspectives to explain vehicle ownership and, as a consequence, mode choice. In contrast to the models with objective explanatory variables, the acquisition of certain transport modes or vehicle types can by no means be described as a utilitarian phenomenon (e.g., as a reduced result of the size of the household or the geographical location in space). This is based on the assumption that degrees of freedom have increased as a result of individualization and localization in modern societies and that vehicle ownership differs primarily according to pluralized mode-related psychologies. In these vehicle ownership models, subjective factors are used for explanation.

Psychological factors used to explain vehicle ownership are theoretically and methodologically complex. Here, action-theoretically founded constructs from transport psychology and microeconomics exist to explain the respective claims of ownership structures. The economic models focus on the idea that people act on the basis of rational economic decisions (time and available budget). From a psychological perspective, this approach is considered to be “subcomplex”, because it does not take into account the manifold inner psychic processes. In transport psychology, at least three constructs based on action theory can be differentiated, which have an influence on the ownership decisions and mode use: these are (1) control beliefs as subjective evaluation of persons by means of vehicle ownership to be converted into certain behavior, (2) attitudes that include cognitive, affective, and behavioral elements related to vehicle ownership, and (3) norms that relate to expectations of social groups or individuals that are considered relevant to one’s own person (Hunecke, 2015). All three dimensions have been shown to play a decisive role in ownership decisions and the associated long-term and short-term vehicle uses. In order to explain individual decision-making processes for ownership and use of transport modes as coherently as possible, the constructs are often integratively translated into action models from psychology, such as the theory of planned behavior or the norm activation model, which in turn can be tested using structural equation models (Article 10408: Modeling Passenger Transport Mode Choice).

The use of psychological variables not only plays an important role in understanding vehicle ownership and use, but is also of political and planning relevance. Bamberg et al. (2003) offer an insightful example of the extent to which the introduction of new mobility tools can result in a psychological upgrading of transport modes, which is relevant to travel behaviors. With the help of the theory of planned behavior in a structural equation model, they use a before-and-after survey to show that the introduction of the

semester ticket—an affordable season ticket based on a solidarity payment system for students—at a German university led to a change in attitudes, subjective norms, and perceived behavioral control, expressed in a stronger intention to use public transportation.

Another example of how psychological variables can be used to affect ownership structures in terms of policy implications is the segmentation of individuals by mode-related psychological factors. Of interest is, for example, which attitude-based groups of people can be addressed for new mobility offers (carsharing, MaaS, etc.). Multivariate cluster analysis methods are suitable for this, with which persons can be combined into groups with homogeneous psychological constitutions. They may already have a specific mobility toolkit at their disposal (e.g., a season ticket for public transport) and may also be attracted to other specific mobility options (e.g., by being open to membership of bike sharing providers). Political decision makers and transport companies could then place their offers specifically where these groups move (e.g., at the physical interfaces of major train stations).

Blurred Lines Between Objective and Subjective Factors: The Role of Built Environment in Ownership Decisions

One problem is that the aspects of vehicle ownership that are treated as objective or subjective cannot always be viewed independently of each other and are even blurred. In recent years, there has been an increased effort to address this problem, as for example the category of built environment. Many studies can establish a connection between the built environment and a specific vehicle ownership structure. However, it often remains unclear to what extent vehicle ownership is a result of the built environment or arises from positive attitudes or individual preferences for residential locations and the transport modes associated with the residential locations [models were prominently offered by [Bhat and Guo \(2007\)](#) and most recently by [Macfarlane et al. \(2015\)](#)].

A common approach is to consider the built environment *a priori* as an explanatory variable for vehicle ownership. Methodologically, for example, using multiple linear regression models, specific spatial indicators — for example, “for example density or diversity” — are analyzed simultaneously with other sociodemographic, socioeconomic, and psychographic factors as explanatory variables. However, in this analysis structure, the complex interactions with the other influencing factors that potentially exist remain invisible. The result is an interpretation that can be criticized as spatial determinism, that is, when vehicle ownership—as it were a natural phenomenon—is to be derived from the structural conditions of the residential location, without additionally taking into account the individual socioeconomic or psychographic conditions behind the decision on the residential location.

Methodologically more sophisticated vehicle ownership models (e.g., the earlier-mentioned structural equation approaches), on the other hand, can show that individuals with mode-related preferences (or other psychological categories) harmonize their ownership structures with the built environment of their residential location; that is, people with an affinity for cars are attracted to a locality that is geared to cars, people critical of cars and with an affinity for active or public transportation are attracted to a multimodal built environment, etc. Here, the vehicle ownership models can sew the content to the concept of residential self-selection, which is based on a spatial self-selection of people according to desired forms of life and mobility (see also the remarks in Article 10379: Residential Location Choice Models). Here, the desired ownership of transport modes is satisfied in complementary spatial structures, that is, in residential locations where the affective connection between human being and transport modes is most in harmony. In this sense, the built environment is reproduced by individual preferences for residential locations and associated transport modes.

Likewise, certain vehicle ownership can also be a result of the built environment. Especially in societies with a strong socioeconomic divide and a tense housing market, social exclusion processes can result in specific groups of people being unable to realize their preferred vehicle ownership on-site. The processes of gentrification in many prospering cities of the global North, in which socially marginalized groups of people in particular are pushed into peripheral locations, should be mentioned as an example. A residential mismatch describes the discrepancy between the preferred and the real mode choice depending on the place of residence. The concept of “forced car ownership” ([Banister, 1994](#)), for example, describes the way poor individuals are forced to buy a car in order to participate in society at all, even though they cannot afford it.

The evidence of concepts such as residential self-selection or a residential mismatch can be methodically considered within the framework of vehicle ownership models if they are implemented, for example, within the framework of the structural equation models mentioned earlier.

New Challenges: New Technologies, New Transport Modes, No Ownership Anymore

New challenges in modeling and predicting vehicle ownership effects exist with respect to the transformation of hegemonic, autocratic transport systems. In the automobile-influenced societies of the global north, research has long focused on the modeling of structures and effects of private car ownership. With the increasing interest in alternative concepts to the automobile such as multimodality—that is, the use of more than one transport mode—further mode options have already been included in the models in recent years. An interest of research in the context of transformation processes of the automobile societies exists in the understanding of new structures and effects with regard to (1) new driving technologies, (2) new transport modes, and (3) new transport systems beyond ownership.

The modeling of new driving technologies is based on purely technical solutions to meet (national and international) climate protection targets and at this level aims to reduce emissions of globally effective greenhouse gases. The models usually focus on hydrogen-based fuel cell technologies or the electrification of vehicles. Since, for example, electric vehicles differ fundamentally from

fossil fuels in certain characteristics (shorter distances, long battery charging times, etc.), modelers are often interested in specific questions as to the extent to which electric vehicles can satisfy the daily transport needs of certain population groups or which specific groups of people are interested in ownership and use with regard to their attitudes and preferences. This interest is usually based on simple economic assumptions, according to which early adopters for emerging market segments are to be identified.

New vehicle ownership structures arise with the emergence of new transport modes. This applies, for example, to the modeling of potential ownership structures of autonomous vehicles with regard to possible effects on individual routes or general mode choices and routing. In this respect, it is assumed that an autonomous vehicle era can result in a reorganization of individual vehicle ownership, which could fundamentally change spatial movement patterns. Researchers are interested, for example, in the extent to which households and individuals could replace their current private transport modes, adapt residential locations in relation to places of work and leisure, and what kind of (social, ecological and economic) consequences this has for existing transport infrastructures (e.g., road capacities, parking needs). Also, individual preferences with regard to lifestyle factors seem to be of interest for the ownership of autonomous vehicles, in order to identify possible early adopters.

Finally, a third challenge in the modeling of transport ownership concerns the emergence of new mobility services, in which vehicle ownership is successively replaced by vehicle usership. Individuals no longer necessarily own their own transport modes, but decide flexibly—that is, entirely in the sense of smart mobility on the basis of interconnected mobility services (carsharing, bikesharing, scootersharing, trains, trams, buses, etc.) using modern information and communication technologies such as the smartphone—on the basis of their memberships which mode is the most suitable for the respective situation, on the basis of their memberships. The autonomous vehicles mentioned earlier can also be a component of such a system. In many economically prosperous cities, technically sophisticated mobility services are already being offered and used. A central question for researchers is to what extent individual behavior patterns produced within the framework of interconnected mobility services can lead to the dissolution of ownership structures in general, thereby achieving green effects in transport, or which social groups participate in the new services in terms of sociodemographic or psychographic characteristics.

Nomenclature

CBD It refers to the Central Business District of an agglomeration where there is important concentration of employment, commercial, and leisure locations.

Dock A dock is a physical system that allows parking and locking a shared bike.

Dockless It refers to a bikesharing system that operates without stations and docks to lock the shared bikes.

First and last mile It refers to the access segments of a transit trip, that is, the distance between the origin and the transit station or between the transit station and the destination.

Geo-fence or electric fence A geo-fence or electric fence refers to the concept of defining a zone with virtual frontiers relying on global positioning system (GPS), radio frequency identification device (RFID), or Bluetooth signals to determine whether bikes are within or near a certain area.

Loop A trip chain starting and ending at the same station.

One-way trip A trip that has different origin and destination stations.

Rebalancing It refers to the operation by which shared bikes are redistributed among the stations typically using trucks.

Trip generation It refers to estimation of the number of trips that are produced or attracted by a station depending on its features (number of docks) and the features of the surroundings (population density, transit stations, etc.).

Introduction

This paper first proposes an overview of bikesharing, namely its origin, its most important evolutions over time, the main components of a bikesharing system, as well as a description of how such system typically works. It then discusses the challenge of designing a system in a city (where and how many stations and how many bikes for instance) as well as the most important challenge with respect to operational planning of such a system, which is the rebalancing of bikes throughout the stations. This leads to the issue of modeling the use of the systems (how many trips, between which stations and at what time) as well as of the behaviors of users, both members and occasional ones. Factors which are the most determinant on the use of a bikesharing systems are afterward discussed, followed by some views on how such transportation mode fits in the multimodal transportation systems of cities as well as on the impacts it has at the city level, namely with respect to sustainable development collective objectives. Key emerging issues are finally discussed.

Overview of Bikesharing

Bicycle sharing or bikesharing refers to systems in which people can rent bicycles for short periods of time to travel either between stations, for systems with docks, or within zones for dockless ones.

The first official bikesharing service appeared in 1965 in Amsterdam under the name Witte Fietsen thanks to the initiative of a citizen which decided to provide 50 bicycles all painted in white for free usage by all citizens. Unfortunately, without any sort

of management, the entire fleet of bikes disappeared within few days. This is said to be the first generation of bikesharing systems.

The second generation of bikesharing systems appeared in the beginning of the 1990s in Denmark, first with small-scale systems and then with City bikes, the Copenhagen system, bringing many improvements compared with the previous generation, namely more robustly designed bikes, usage management through coin deposit and stations. Still, such system was facing important theft issue due to the low cost and anonymity of users.

The third generation of systems addressed this issue with improved users (and bikes) monitoring and introduction of pricing of usage. People must register or at least provide some sort of identification and bank account to be able to rent a bike, consequently discouraging bad usages or thefts. It is the 2005 Lyon's Velo'v system, with 1500 bikes, that really consolidated this third generation of bikesharing system, due to its large scale and noticeable impacts. Many other systems followed in Europe, Americas, and Asia, and all contributed to increase the interest toward this innovative urban transportation mode.

Improvements for the fourth generation include mobile docking stations that can be moved around to fit user demand or that can be stored when weather conditions are not suitable to operate such system (as it is the case for the Montreal's bixi system which only operates from April 15 to November 15 due to cold weather and snow during the other months) as well as the use of local energy sources for the stations such as solar panels.

Readers are invited to read [De Maio \(2009\)](#) who provides further insights into the history of bikesharing.

The main components of station-based bikesharing systems are the bikes, the stations, and the docking points. Bikes typically are constructed to prevent access to internal components and limit the risk of breakage or piece theft. They are robustly designed and made accessible to a diversity of cyclist. A robustly design, fourth-generation shared bike from the Montreal bixi bikesharing system, is presented in [Fig. 1](#).

Stations (example presented in [Fig. 2](#)) are composed of a kiosk to allow users to make transactions such as buying a day pass or choosing a bike and docking points. New systems also allow to directly take a bike without interacting with the kiosk while some stations do not provide a kiosk and users must make their transactions with their phones.

In the recent years, we have seen the comeback of bikesharing systems without stations. But such systems have nothing in common with the first generation of systems. They are called dockless bikesharing systems and use bikes equipped with GPS

Figure 1 Example of a share bike from the Montreal bixi bikesharing service. Source: Image provided by bixi Montreal.

Figure 2 Example of a station from the Montreal bixi bikesharing service. Source: Image provided by bixi Montreal.

(or other technologies) allowing to locate the bikes at any time as well as onboard systems to allow starting/ending a rental without requiring a physical docking point. Hence, bikes are monitored through technology and users access the bikes using their phone. It must be noted that dockless systems are more vulnerable to vandalism and theft. While they are appealing for users since they do not need to bother about finding an empty dock to leave their bike or walking from the station to their destination, such system may create chaos in cities if rules regarding where bikes can be left are not clear and enforced. One way of managing the areas where bikes can be returned after usage is through geo-fences. Instead of allowing bikes to be left anywhere within a certain area, it may be useful to prevent misbehaviors and to control specific small zones where bikes can be left using geo-fences (or electric fence).

Designing a Bikesharing Service

Depending on the systems, the number of stations and docks per station will vary, from a few in lower density areas to few hundreds or more in central parts of the city or near important trip generators and transit stations. The design will depend on the market potential in the various areas, in terms of membership (hence related mostly to population density and sociodemographic composition) and trip generation (depending on types and density of interest points). Various attributes will determine the production and attraction potential of a station. Determining where to implement the stations, how many to install, as well as how many docking points to include in each station are important design questions that will have an impact on the number of members that will adopt the service as well as on how many trips each station will support. This problem is often referred to as the location-allocation problem and proposed models to assist in the design will aim typically to minimize impedance (minimize distance between stations and demand) and maximize coverage (maximize the population covered by the stations). The set of stations also needs to provide good coverage and connectivity in the sense that stations should not be too far away from each other, especially when expanding the network in more residential areas. According to US and Canadian bikesharing operators, optimal distance between stations varies between 275 and 400 meters (Shaheen et al., 2012). The distribution of stations throughout a system can be assessed using indicators such as density of stations, area covered by stations, compactness, and distance between stations and number of stations (Médard de Chardon et al., 2017).

Since bikesharing most plausibly will not be able to provide an answer to all transportation needs, it often works well when implemented where other transportation alternatives are available, namely transit. Moreover, since it allows users to do either one-way trips or loops, it can be used in combination with other modes, to access transit for instance or to come back from work in the afternoon while traveling by transit in the morning. There is no consensus among operator with respect to optimal distance between a bikesharing station and a transit station but it is as low as 25 meters for large-scale systems with good public transit systems (Shaheen et al., 2012).

Regarding the number of bikes, it is also an important feature of the bikesharing system. Actually, the ratio between the number of bikes and the number of docks is a key indicator to account for when designing a system. Too many bikes per dock will facilitate access to shared bikes but will make it harder to find an empty dock at the end of the ride while too few bikes per docks will make it hard for users to find a bike but those who do will typically not have issues finding an empty dock to return it. Most system will aim for a ratio of two docks per bike, but it can vary a lot, namely if we account for system failures (damaged bikes or docks) (Shaheen et al., 2012).

Another important design component is the pricing scheme. In most systems, users of the bikesharing systems are either members or occasional users. In the first case, people register as member for various time periods (month, year) and can use the shared bikes as often as they want without further cost as long as their trips are under a time threshold (typically 30–45 minutes). In the second case, they either buy a short-time access, 24–72 hours for instance, and or have free rides as long as they are under the time threshold or pay for a single use.

In the context of network development, the design question will narrow down to identifying potential zones for extension. In such case, potential market must be assessed and impacts on the generation of new trips as well as on the spatial-temporal structure of the trips require modeling.

Operational Management: The Challenge of Rebalancing

On a day-to-day basis, a bikesharing operator must continuously assess whether the bikes are in the right stations or whether some docks need to be emptied. This challenge, faced by most if not all bikesharing operators, is referred to as rebalancing or more precisely bikesharing rebalancing problem (BRP). Many developments have been made with respect to algorithm and approach to assist operators in anticipating where bikes must be relocated to meet travel demand. These algorithms perform short-time predictions of the optimal state of the system and optimize the boarding/alighting movement over a truck route while accounting for various constraints such as the number of bikes in the system, the capacity of each station, the number of vehicles available, as well as their capacity (in number of bikes they can transport).

The reason why systems must be rebalanced is due to spatial heterogeneity of demand over time. Typically, in the morning period, trips will dominantly start in stations located in residential areas, usually further from the CBD, and end in stations located near points of interest, namely centrally located. This is typically referred to as commuting patterns. Hence, stations used for departure will be emptied by users while those located nearer to important activity locations (work, study) will be filled by users

returning their bikes. Rebalancing will thus be required to ensure users in residential locations can access bikes and users heading to central areas find empty docks. Topography of the city can further enhance the issue of origin–destination asymmetry since stations located on top of hills will be less likely to be chosen as destination stations and will continuously require to be filled, the reverse being true for down the hill stations that will be more rapidly filled. Of course, this issue will lessen if the bikes have electric assistance.

Various indicators can be estimated to assess the quality of service from the user point of view such as the proportion of time a station is empty and the proportion of time a station is full. In both cases, the user may have difficulty either finding a bike or finding an empty dock to return the one he has. Other performance indicators can be estimated such as the ratio of bicycles docked versus capacity per station, the proportion of damaged bikes daily, the utilization rate, that is, the total bicycle-minutes of usage versus the total bicycle-minutes of availability per temporal unit. With respect to the operator, operating cost must be minimized since daily redistribution of bikes using trucks is an important component of these costs and also affects the perception of bikesharing since some argue that the environmental gains of making bikes more available for daily travel is cancelled by the motorized vehicle-kilometers traveled by these redistribution trucks.

Understanding Bikesharing Usage

The way bikesharing systems are used is examined either from a system-wide perspective or from a user perspective. Administrative data from bikesharing systems, when available at the trip and member level, allow conducting both types of analysis.

Analysis at the system-wide level focuses on the estimation of daily trips generated per station (either trips starting, ending, or the sum of both), depending on various features of the stations. Station features which were found to be more determinant of the number of trips observed per stations are number of docking points, altitude of the stations, population density, employment density, proximity to a university/college, distance to nearest stations, density of points of interest, proximity to transit, and availability of cycling infrastructures. Global trips per day per bike and its variability throughout the months can, for instance, be used to compare the performance of various systems (Médard de Chardon et al., 2017). Various types of models can be used to explain and forecast total number of trips per station such as regression models, ordered logit models, or spatial expansion models. Models were also developed to understand and forecast origin–destination matrix between stations. Travel time or distance, on the bike network, is used as input in distribution models that aim to reproduce the spatial structure of trips.

Analysis at the user level focuses on the understanding of usage patterns by users. But first, study using both administrative data and surveys helps assess the dominant features of users. While characteristics vary across systems, the most typically reported attributes for becoming a member are: typically men, younger than the average population (typically below 30–35 years old increases probability of being a member), home location near to a station, both students and working people.

Hence, it is frequent that users will be classified based on their usage patterns using clustering methods. Typologies often segment users based on their frequency of use (from hardly use to frequently use), their seasonal pattern of use (mainly during the 2 summer months or during the entire season), their weekly behaviors (weekdays during peaks or weekends), the diversity of stations they use, the structure of their trips (one way or loop), the distance/duration they travel, or the fact that they combine bikeshare with other modes such as transit. All these indicators are useful to apprehend usage, identify potential markets, and forecast the impacts of design scenarios.

Hence, various factors have been confirmed as having an important impact on bikesharing usage. Some factors are structural and will promote the use of cycling, both private bicycles and shared bikes. These factors are built environment (namely route pattern and diversity of usages), topography (hilly areas make cycling more challenging), cycling infrastructures, safety of the available route (related not only to available of infrastructures but also to traffic speed and flow), and features of the trip itself such as its length and the time period when it is done. Other factors will cyclically or punctually affect cycling and bikesharing usage such as weather. Typically, the use of cycling will increase as the weather gets warmer but it will start to decline again when temperature exceeds 30°C or so.

Due to unfavorable weather conditions, many systems in the northern hemisphere will either stop operating during winter or reduce their capacity. Some fourth-generation systems will actually be fully removed from the streets during the winter period due to cold and important snowfalls. While some users will make bikesharing throughout the operating season, clement weather will favor increased usage of bikesharing. Additionally, rain will, on the contrary, significantly reduce the number of trips occurring on the network (both rain forecast and current rain). Other types of events, either planned (match or show for instance) or unexpected (subway breakdown), will also change the typical behaviors and will increase demand punctually in specific locations. This will complexify the rebalancing issue; still, with good short-term forecasting models including planned events, network can be planned according to expected travel demand.

How Bikesharing Fits in the Multimodal Urban Bouquet of Transportation Modes

With the diversification of alternative modes of transportation, there has been increase interest into how to coherently integrate all these services to provide the required tools to meet the entire set of travel needs, as a global aim to reduce the place of private cars in cities. Concepts such as Mobility as a Service (MaaS) or integrated mobility have emerged to frame the interaction between modes

and envision services that are planned and provided in batch. Hence, the question of the role bikesharing plays in an urban bouquet of transportation modes has become more and more relevant. Both competitiveness and complementary interactions have been examined to understand which modes in which contexts should be favored.

Results of these analyses point to the fact that bikesharing may be competing with taxi for short trips during the summer months while transit and bikesharing have a more complex relationship, bikesharing sometimes facilitating access to important transit nodes (first and last mile transit issue), replacing transit trips, or compensating for transit unavailability during night period, closures, and disruptions for instance. Research has found that bikesharing both decreases and increases transit ridership, while the decrease, when observed, was very low. Hence, long-term perspectives must be added to trip-based analysis since, in the long run, availability of more than one option may prevent someone from buying and using a private car. Further discussion on the interaction between transit and bikesharing can be found in TCRP 132 ([National Academies of Sciences Engineering and Medicine, 2018](#)).

What are the Impacts of Bikesharing in Cities?

Bikesharing has reinvented the way people use bicycles to move around cities. It has also confirmed that cycling can be part of the transportation systems that cities can rely on to reduce dependence toward the car. Various studies have assessed the impacts of bikesharing in cities such as health impacts, environmental benefits, GHG reduction, decreased automobile use, increased mobility, promotion of cycling as a travel tool not only a leisure activity, and congestion reduction. An important component of such assessment is to be able to estimate what would happen with the trips currently done using bikesharing if there was no bikesharing system available: would they be traveled using another mode of transportation and if so which mode would be selected. Hence, results vary according to system size (stations and bikes), city scale, demographic composition (namely income and car ownership levels), and quality of the available transit system. Regarding the health impacts, estimations show that the health benefits of the physical activity related to cycling are more important than the increased risk of traffic fatalities and air pollution for those who cycle ([Otero et al., 2018](#)). Hence, at the individual level, in addition to its contribution in staying fit, bikesharing is a cheapest travel option than private car or even transit and can contribute to reducing travel expenditures for household.

Next Steps

The sharing economy has changed the way people access to services. Many cities have seen the proliferation of station-based carsharing services, free-floating car services, and dock and dockless bikesharing systems. More recently, e-scooters have been invading cities, requesting them to seriously address the issue of road sharing and shared vehicle managements. People are rapidly adopting these agile transportation modes that offer them high flexibility and accessibility at low cost, but integrated planning still is a step behind. Travel choices have become highly dynamic as they adapt to available options at the time of travel. Cities will need to plan the transportation systems in an integrated way and account for the travel needs and system requirements while aiming for the optimal combination from the global sustainability point of view.

Background

Carsharing is a type of shared mobility that allows short-term access to a car. Carsharing services can be traced back to 1948 in Germany. However, they increased in popularity with advances in information and communications technology (ICT) (Shaheen et al., 2016). Carsharing can influence transportation systems, energy systems and city development through changes in travel behavior, land use as well as the creation of new businesses.

There are several different schemes for carsharing in the market. Round-trip station-based carsharing was the first form of carsharing introduced and is still the most widespread. In this carsharing scheme, users pick up a car from a station and return it to the same station after use. This carsharing scheme can be resource-efficient for operators, but less flexible for users. One-way carsharing services (station-based and free-floating) are more flexible schemes offered to the market by operators. In one-way station-based carsharing systems, users do not need to return cars to the station of origin. In free-floating services, users can pick up and return cars to any location within the business area of these services, which is usually the city center. One disadvantage of this flexibility is the lower reliability in terms of availability of shared cars. Due to different pricing and service schemes, the usage patterns (specifically in terms of rental duration and distance traveled) and user groups of free-floating services might be different from those of station-based services (see e.g., Becker et al., 2017a; Kopp et al., 2015). The research on free-floating services, including their impact on sustainable transport indicators, has been less-developed. The relative newness of the services, the lack of relevant data, and the additional complexity presented by the fact that the cars could be anywhere, pose major obstacles to research. Currently, four different carsharing markets exist: business-to-consumer, business-to-business, peer-to-peer, and not-for-profit. In the business-to-business model, employees are provided access to a carsharing organization's fleet through their employer. Peer-to-peer carsharing services allow car owners to make their personal cars available to be shared on a short-term basis. In this chapter, the focus will only be on business-to-consumer carsharing since this is the type that has been most extensively studied.

Despite its small mode share, carsharing is growing throughout the world and becoming recognized as a new transport mode. It is therefore crucial to develop transport models in which carsharing and other new mobility services are explicitly modeled in order to assess their impacts. These models can be used by policymakers to include these services in future planning processes and predict different future scenarios. Moreover, these models help operators to design efficient and frequently used services. This chapter overviews the modeling efforts in the area, addresses the limitations and research gaps and discusses future research. It starts with data used for modeling and continues with the modeling of different sectors of carsharing, that is, demand and supply and their interaction. The focus of the chapter is mainly on the demand side.

Data

Different data sources have been used in the literature to study carsharing services. These sources are introduced below.

Revealed Data

Revealed data in this field usually comprise membership and usage data obtained from the operators. This source of data is limited in that it does not provide any information about nonmembers. Therefore, it does not provide a basis for comparison and is consequently not appropriate to studying changed travel behavior or to estimating choice models. However, this type of data could be suitable for validation of simulation models.

There is a relatively new source of data, specifically in the field of free-floating carsharing, that is obtained by web scrapping (see e.g., [Kortum et al., 2016](#)). Web-scraping methods enable the collection of real-time data from publicly available information. The technique simulates a user requesting available information to book a car from operators' website, but is performed in an automated and repeated way, for example, every 60 s. This source of data is good for studying trip characteristics and spatiotemporal distribution; however, it does not provide any information on users or purpose of trips.

Surveys

One of the most common approaches to studying carsharing travel behavior is to use surveys. The questions of interest in surveys are usually users' characteristics, lifestyles and attitudes as well as changes in travel behavior after joining carsharing such as changes in private car ownership, vehicle miles driven, or transport mode taken. However, in the majority of behavioral change studies, the observed behavioral changes are attributed to carsharing membership and the correlation is assumed causation. Yet there could be a common underlying factor, such as a life event, or structural issues, such as access to public transport, that affects both carsharing membership and travel behavior changes (endogeneity issue). The possibility of endogeneity issue could lead to systematically overestimating the impacts of carsharing ([Le Vine and Polak, 2015](#)). A few studies have controlled for these issues by including a sample of noncar sharers (see e.g., [Cervero, 2003](#); [Kopp et al., 2015](#)).

Another methodological issue with surveys in the field is recall bias ([Becker et al., 2017a](#); [Kopeck and Esdaile, 1990](#)). In these surveys, respondents are usually asked about their travel behavior (e.g., vehicle miles traveled) before joining carsharing, and the assessment is therefore based on self-reported data. One way to overcome this bias is by designing a survey in multiple waves of before-and-after joining carsharing (see e.g., [Cervero and Tsai, 2004](#)).

Travel Surveys

Travel surveys or travel diaries are often the largest and most reliable data sources available to transportation researchers. Travel surveys include data on individual travel behavior, capturing all activities and trips during a predefined period. However, carsharing has not been included in travel surveys in many countries. An essential future effort in modeling carsharing services is to explicitly include them in travel surveys.

Stated Preference

Stated preference (SP) choice experiment is another type of survey used to study carsharing services. These experiments are designed to measure preferences for different attributes of carsharing services. Small scale and being based on a nonrepresentative sample of the population are the major limitations of the majority of the stated preference choice experiments in the field.

Methods

There is a large descriptive body of literature that deals with carsharing membership, user characteristics and travel behavior, but modeling approaches are still limited. The most important challenge is data. Models are expected to be policy-sensitive so that they can be used by practitioners and policymakers to test different future scenarios. Thus, extensive data sources on individuals' socio-demographics, travel behavior, travel needs, and attitudes are required. All these data are not necessarily accessible and available, especially data on newer services. In many cases, stated preference surveys are required, which are costly and might not be representative. Below, modeling efforts in the field for both the demand and supply sides are discussed. The focus of the chapter is mainly on the demand side.

Demand

Although the popularity of carsharing is increasing worldwide, the estimation of travel demand for this mode has only rarely been addressed by researchers. In this section, the literature on demand modeling and its limitations and gaps is reviewed.

To be able to choose carsharing as a transport mode, one first has to join a carsharing organization. This section thus starts with different membership models and continues on to trip demand models that deal with the day-to-day demand for carsharing services.

Membership Models

Membership models explore the market potential for carsharing services by identifying potential members. These models investigate the factors affecting the intention to join a carsharing organization. Similar to car ownership models, these models are estimated at the person level and are used to predict mid-term strategic travel choices that influence trip-level decisions.

In the majority of studies, membership models are estimated using discrete choice models. In the absence of member characteristics, Kortum and Machemehl (2012) use regression models to predict the proportion of population of a census block that are members of free-floating carsharing given the probability of that block to contain any members. To the best of our knowledge, this is the only study modeling the membership of free-floating services.

Early attempts to identify carsharing membership potential mostly focused on socio-demographics and annual private car mileage to find a breakeven point between ownership costs and sharing costs. Later on, aspects such as neighborhood factors, individuals' travel patterns, carsharing attributes, individuals' attitudes, and environmental concerns have been added.

However, most models in the field have limiting assumptions. The main limitations are described in the following paragraphs.

Supply-side attributes are known to affect potential membership for carsharing. However, only a small number of studies have included the attributes of carsharing services or supply-side aspects in membership models (see e.g., Juschten et al., 2019).

Another common limitation of the majority of membership models is that they do not include other alternative mobility options. The choice of becoming a carsharing member is a choice of a mobility resource, that is, product, service or knowledge that enables travel (Le Vine et al., 2014). To incorporate other mobility resources as explanatory variables in membership models might lead to endogeneity issue, as discussed earlier. The challenge of modeling the choice between different mobility resources is that mobility resources are not mutually exclusive. One way to overcome this problem is to estimate every possible combination of mobility resources and define a mobility portfolio, as in Le Vine et al. (2014). Another approach is to account for correlation in error terms between choices by employing, for example, a multivariate Probit model (see Becker et al., 2017b).

Another limitation is that most researches ignore the role of individuals' attitudes and lifestyles in carsharing decisions. Attitude and satisfaction have been addressed by a few studies employing hybrid choice models (see e.g., Kim et al., 2017). Hybrid choice models (Ben-Akiva et al., 2002) incorporate latent attributes such as values, social norms and lifestyle based on a set of observable indicators.

Finally, becoming a carsharing member does not necessarily mean becoming an active member, that is, using carsharing as a transport mode. Morency et al. (2012) and Habib et al. (2012) identify active members with dynamics of habit formation, that is, linking the decision to use the carsharing service to the user's previous usage decisions in a defined period, that is, 4 months.

Travel Demand

Travel demand refers to day-to-day trips made using carsharing services. These decisions are made at the trip-level and are conditional on the decision of becoming a carsharing member. There are a few studies that model the modal split of these services. The majority of these studies are based on stated preference experiments due to the lack of suitable data. However, trip-level demand models might not be appropriate tools to model travel demand for carsharing services. Studies show that car-sharers are purpose-oriented, flexible, multimodal and intermodal. Additionally, characteristics like reservation prior to use and distance-time price structure of carsharing services further encourage users to plan their activities and their daily schedules. Therefore, considering only one trip, as in trip-level models, might not be representative for this type of travel behavior and the entire daily tour might need to be considered, as in activity-based models. Moreover, carsharing is a service with limited supply in terms of both fleet size and stations. Therefore, the accessibility and reliability of these services have a determining effect on the choice of these services (De Lorimier and El-Geneidy, 2013). Accessibility is determined by the distance between the position of the user and the positions of the stations/cars. Reliability is the availability of cars when they are needed. Furthermore, shared cars compete with private cars for infrastructure in terms of both roads and parking spaces. All these attributes make the demand for these services supply-sensitive, and accounting for these attributes requires high spatial and temporal resolution.

A new research direction was introduced by Ciari et al. (2008), who address the above-mentioned aspects by employing an activity-based agent-based microsimulation using MATSim (Balmer et al., 2008) as the platform. This type of models allows for a very rich description of both individuals and infrastructure and therefore explicitly accounts for the complex links between travel needs and supply attributes in order to predict carsharing demand. It simulates the daily activities and travel of each agent. All of these come at the cost of being computationally intensive. Moreover, the agent-based modeling approach is mainly based on the behavioral rules defined at the microlevel and therefore does not rely much on past information to make predictions (Ciari et al., 2013). This modeling approach is thus an appropriate tool for new mobility services, for which past data is often not readily available. This also presents a big challenge regarding calibration and validation of the models. One limitation of the majority of carsharing simulation studies is that they only address one day of simulation. However, studies show that the demand for carsharing change over different days, especially weekdays versus weekends. The study of Heilig et al. (2018) is the first to simulate carsharing for more than one day using the agent-based approach and therefore analyzes the variability of carsharing usage.

Although simulation gives a very detailed representation of the carsharing system in general, it only provides a snapshot of the situation. The long-term effects are not directly within the scope of the simulation. Regression models have been used to explain long-term demand (see e.g., Becker et al., 2017c; Schmöller et al., 2015). These models relate carsharing demand to service attributes, neighborhood/city characteristics and demographic factors. These models are at zonal spatial resolution.

Finally, data mining techniques are another method employed to identify spatiotemporal patterns of usage characteristics such as usage frequency, traveled distance, usage variability as well as characteristics of users (see e.g. Schmöller et al., 2015). Recently, advances in data methods and access to big data have made data mining techniques more popular.

Supply

The supply of carsharing services has a huge impact on the demand for these services. Despite the existence of very detailed carsharing simulation models, models to accurately represent supply are rare. In this section, the overall challenges in modeling the supply side are covered.

Optimization of infrastructure, that is, location and capacity of carsharing stations, and fleet management, that is, fleet size planning, relocation strategies, pricing and refueling/charging are the main objectives in a carsharing operation system to maximize the profitability of the service (Ferrero et al., 2018). Much of the literature on one-way systems (station-based or free-floating) is focused on vehicle relocation. Vehicle relocation is the transfer of cars from stations or areas (in the case of free-floating carsharing) with higher vehicle accumulation (unused cars) to stations or areas experiencing a vehicle shortage in order to improve the performance of services. Relocation models investigate the trade-off between cost and availability. Dynamic pricing policies can increase profits for operators as well as improve the balance of the system (Jorge et al., 2015). Determining the operating area is another important issue on the supply side.

The supply models are, in general, developed for one-way carsharing systems. Modeling the supply side of free-floating services can be particularly challenging since cars can be everywhere. The two major methodologies used in supply models are simulation (e.g., agent-based or discrete-event) and optimization (see e.g., Correia and Antunes, 2012), as well as a few mixed approaches (see e.g., Jorge et al., 2012). Most of the simulation models are at the disaggregate level of users and vehicles but do not necessarily provide optimal solutions, while optimization models provide optimal solutions but at an aggregate level (Nourinejad and Roorda, 2015).

A small number of studies investigate the supply-demand relation (see e.g., Ciari et al., 2016; Martínez et al. 2017). A future direction of research in the supply side would be to determine the optimal solutions based on the demand model. In the majority of supply studies, demand is given, and origins and destinations are considered random.

Gaps, Further Research and Final Words

The main objective of this chapter is to highlight the importance of developing modeling tools for carsharing in the near future. Extensive literature exists on carsharing travel behavior but understanding its effects on the transportation system requires additional modeling efforts. Forecasting the impacts of these services on travel demand, transport network, and land use patterns requires the development of policy-sensitive models. The increasing popularity of these services, their expected future growth and the possible integration of shared autonomous vehicles into the picture make the need for such tools even more essential. The main obstacles to such models are lack of data, which is usually not shared by companies, as well as behavioral complexity. Using sophisticated models to answer complex planning questions requires large datasets incorporating extensive independent variables.

A further step in carsharing demand modeling is to integrate these models into larger travel forecasting model systems used for long-term transportation planning. To do so, travel surveys should explicitly include these services as distinct modes. Further development of disaggregate choice models that incorporate these services explicitly as choice options are necessary.

Further research is needed to address user short-term and mid-term response to uncertainty in availability of carsharing system as well as user preference for spontaneous booking versus prior booking.

To conclude, carsharing as other new mobility services will benefit from any methodological contribution to both supply and demand sides to verify its application as a transportation mode and its contribution to sustainable transport indicators.

Biographies

Shiva Habibi is a senior researcher at RISE - Research Institute of Sweden. She holds a Ph.D. in Transport Science from KTH - Royal Institute of Technology, Stockholm, Sweden. Her research aims to understand the decision-making process of different agents in transportation systems and develop models to predict their responses to different policy and marketing intervention. Her research interest include transport planning, transport demand modeling, transport policy as well as innovative mobility services.

Frances Sprei is an Associate Professor in Sustainable Mobility. She has a PhD in Energy and Environment from Chalmers University of Technology in Sweden. Her research assess different mobility services such as electric vehicles, carsharing, and autonomous vehicles and studies their adoption and diffusion. Her methods are interdisciplinary and she takes into consideration technical, economical and behavioral aspects.

Definition

The *Macquarie Dictionary* (2017) refers to “recreate” as “to refresh by means of relaxation and enjoyment, as after work; to restore or refresh physically or mentally.” Yukic (1970, p. 5) states that “recreation is an act or experience, selected by the individual during his/her leisure time, to meet a personal want or desire, primarily for his/her own satisfaction.” Mercer (2003, p. 412) shows that “recreation refers to activities, either active or passive, enjoyed either outdoors or indoors, which take place during leisure—as opposed to non-work—time.” In addition, the Fifth Edition of *The Dictionary of Human Geography* (Gregory et al., 2009, p. 624) defines recreation as “pursuits or activities (even inactivity) undertaken voluntarily outside paid employment for the primary purpose of pleasure, enjoyment and satisfaction.”

Confusion may arise over the use of the terms “recreation” and “leisure,” which are closely related and often used interchangeably. The simplest difference identifies recreation with activity and leisure with time. Recreation is an activity, for example, play, that amuses, stimulates, or diverts while leisure emphasizes the freedom in time obtained through the cessation of activities. In other words, you could be at leisure, but not necessarily engage in recreational activities. For example, you could just sit somewhere and do nothing. In addition, we need to distinguish between “recreation” and “tourism.” Tourism is commonly discussed in the context of recreation and leisure: the majority of tourism is recreational, in that tourism takes place during leisure time and often for the purpose of personal satisfaction and pleasure. Britton (1979) makes a distinction that recreational travel inclines to be private, self-service engaging, whereas tourism concerns services provided by diverse agencies. Gunn and Var (2002) assign an emphasis on profit-making and economic aspects to tourism, while link recreation basically with noncommercial purposes.

Recreational travel involves travel for recreation. Urban recreational travel shares with commuting travel regarding short-term and reversible characteristics. They differ from each other in that commuting travels take place, for most people, at fixed times on each working day, and between fixed origins and fixed destinations, whereas recreational travels have only fixed origins—the home in most cases, and in every other aspect they are discretionary. The 2017 US National Household Travel Survey (NHTS) (US Federal Highway Administration, 2019) classifies social/recreational trip purposes into three categories: performing recreational activities (e.g., visit bars, parks, museums, or movies), exercising (e.g., walk, walk the dog, go for a jog, or go to the gym), and buying meals (e.g., go out for meals, snacks, or carry-out).

Urban recreational travel is by no means an insignificant segment of total trips made by citizens. In many cities, recreational travel accounts for a relatively high proportion of total individuals’ trips, from one-third to one-half (Anable, 2002; Ohnmacht

et al., 2009). The 2017 US NHTS Report (US Federal Highway Administration, 2019) shows that trips for social/recreational activities increased in proportion every year, rising from 22% to 32% of the total discretionary trips between 1990 and 2017. The European Council of Ministers of Transport (European Conference of Ministers of Transport, 2000) observes that growth in recreational travel (and activities) could be related to three main reasons: increasing living standards, earlier retirement, and the trend toward shorter working hours. Therefore, with the continued rise in individuals' leisure time and economic prosperity worldwide, the demand for recreational travel is expected to increase (Misra and Bhat, 2000).

Travel Patterns

Temporal and Spatial Distribution

Essential to the recreation experience is the freedom of selecting the activity, location, and time. Recreational travel starts any time during the day, with the majority occurring during the off-work time. Certain definite temporal patterns on an hourly, daily, and seasonal basis can be identified, depending on the specific activities and their spatial locations relative to individuals' place of residences. The spatial distribution of trips is determined by the location of recreation attractions and the location of individuals' homes. The place of production is essentially an individual's home; the place of attraction usually refers to the recreation location. An exception is possible, for instance, pleasure driving, with no single point of attraction. Travel distance is characterized by the time available and cannot exceed a certain maximum.

Both numbers of recreational trips and distance traveled vary by day of the week, with much more trips and longer distances of travel on the weekend. An analysis of New Zealand Household Travel Surveys 2003–6 shows that 40% of social and recreational trips and 47% of the distance traveled take place on the weekend (Witten and Mavoa, 2011). According to the 2017 US NHTS Report (US Federal Highway Administration, 2019), there was not a clearly discernible trend in terms of trip distance or duration over the past decades: social/recreational trips remain almost the same (averaged at 8.6 miles (13.8 km)) in trip length but vary in duration (20.8 min in 2001, 19.7 min in 2009, and 22.2 min in 2017). But temporal distribution by the time of day keeps consistent: social/recreational travel peaks at the 12 a.m. and 6 p.m. hours.

Travel Mode Choice Characteristics

It is observed that the car is commonly used for recreational travel (McGuckin and Fucci, 2017); it offers the most freedom in selecting any destination and in timing a trip, and provides a relatively high degree of comfort. The use of public transit depends on different criteria: timing of a trip is an important one because public transit is operated on a fixed schedule. This is usually acceptable for attending sport/concert events, and other schedule-bound activities, or activities confined in a limited area such as low emission zones. Another criterion is the convenience of carrying equipment. Public transit will not be a good option unless the equipment is packed in a way that is easily carried. The recreational activity itself is also a criterion in the choice of travel mode. Sightseeing, for instance, leads to riding public transit. Sightseeing tours in cities are well known and might attract people from those who are fed up with driving.

Travel mode choice characteristics are different, contextualized in the physical and social environments of a country/region. An analysis of New Zealand Household Travel Surveys 2003–6 (New Zealand Ministry of Transport, 2007) shows that 45% of trips were made as car drivers and 32% as car passengers, 19% by walking and 2% by bicycle. According to the 2017 US NHTS (McGuckin and Fucci, 2017), American people conducted 77.1% of social/recreational trips by private vehicles, 1.6% by public transit, and 18.1% by walking. As expected, people living in households with few vehicles reported few social/recreational trips. However, residents in Nanjing (China) were more apt to use walking (77%) and public transit (10%) for recreational trips, on the basis of data analysis from 2013 Nanjing Travel Survey (Nanjing Institute of City and Transport Planning, 2013).

Influencing Factors

Recreation Demand

Human Factors

Personality and cultural background are of significant relevance to recreation demand (Johnson et al., 2001). Kaplan (1960) observed that residents in the same town with different cultural backgrounds (e.g., Africans and Jews) conducted different recreational activities. Africans tended to chat with friends and hangout near the neighborhood while Jews participated more in reading, listening to music, and other intellectual activities. Individual's sociodemographics (including age, gender, income, household structure, etc.) also exert influences on activity participation. Liu et al. (2008) found that the elderly people seem to be more involved with passive activities (e.g., playing chess and cards, chatting), while the young people are more likely to conduct active ones (e.g., sporting, singing).

Social Influences

Social pressure (or peer pressure) is an important factor selecting recreational activities (Shaw et al., 1996). If playing tennis is the current popularity, many people will tend to join tennis clubs. If attending cultural events is "the thing to do" in the neighborhood,

many people will follow doing the same since an immediate neighborhood usually has a common social background. In addition, the social environment might also influence recreation participation. Social environment refers to the neighborhood sociodemographic composition (e.g., unemployment rate, the percentage of low-income people) and social ties (e.g., trust, cohesion) of people living in the neighborhoods (Wang and Lin, 2013). Research findings in the field of sociology suggest that the social environment has strong impacts on individuals' behaviors, for example, the intensity of physical travel (Zastrow and Kirst-Ashman, 2006). Studies in public health also indicate that people residing in an environment with intensive social interactions are more likely to gather regularly with neighbors and friends (Leyden, 2003).

Government Policies

Government has an interest in how its residents make use of their free time because recreation is important to their quality of life. Government policies including educational efforts, financial subsidy, and distribution of free time are important to recreational activities (Leonhardt, 1971). School programs are able to influence recreation participation, for example, a tennis program can contribute a great deal to the growing number of tennis players. Financial subsidies for developing recreational areas and enhancing their accessibility can improve an area's attractiveness. Government policies also impact the distribution of free time. Creating several 3-day weekends when local holidays are celebrated on a Friday or Monday will increase the number of recreational activities. The proposal of "flexible work schedule" may also shift the way people spend their free time.

Economic Environment

Recreation cost and personal income are an individual's primary economic considerations. Clawson and Knetsch (2013) identified positive correlations between disposable personal income and recreation participation. Directly related to income is the cost of participation. For example, low-income people cannot afford high transport costs. User fees of recreational amenities are subject to the type of activity and the ownership of recreational facilities. Public facilities, for example, parks, are usually offered at low cost or free of charge, while privately owned areas operate at market price, for example, golf courses.

Climate and Atmospheric Impacts

The type and amount of seasonal participation depend largely on climatic factors (Leonhardt, 1971). Too hot or cold/wet seasons are not attractive for outdoor recreational activities; the preferable outdoor recreation season is spring or fall in most countries. The impact of weather is also powerful on recreation participation (Smith, 1993), in particular at weekends. The longer the planning period, the less influential the weather on the determination of recreation demand. Air pollution, for example, smog, also affects individuals' outdoor recreation.

Recreation Supply

The role of urban form, land use, and the physical aspect of the living environment—the built environment—in shaping travel demand has consistently been a topic of great interests in travel behavior analysis. Ewing and Cervero (2010) suggest that the following 5Ds of the built environment affect travel: density, diversity, design, destination accessibility, and distance to public transport. A review of 17 studies shows that walking as a travel mode of recreational trips is strongly associated with living in high-density residential neighborhoods and close proximity to destinations (Saelens and Handy, 2008). The type of recreational supply available with the urban area depends on not only the geographic environment (e.g., flat/hilly surfaces, sunny/shaded sidewalks, green spaces and parks), but also man-made facilities (e.g., chess/card rooms, basketball courts). Quite several studies document the connection between the number of recreational facilities and the level of participation in recreation. For example, Li et al. (2005) conducted a survey of 500 elderly people from 56 neighborhoods in Portland, Oregon, observing that the area of green or open spaces and the number of recreation facilities are highly associated with levels of walking.

Transport

Recreation demand and supply are usually generated at different spatial locations. To link them, some means of transport is needed. Surface transport—car, public transit (bus and rail), walking—are the predominant modes. The ability to provide accessibility is an important characteristic of transport. The better the transport service, the more intense the interchange of demand and supply. Enhanced transport service facilitates and encourages participation in recreational activity.

Car plays a leading role in recreational travel (McGuckin and Fucci, 2017). Cars allow for the flexibility in the selection of location and the timing of recreational trips. They provide the convenience of carrying large amounts of baggage and equipment from "door to door" with the minimum trouble for recreationists. Yet, recreation sites need to build enough parking lots, which sometimes is difficult due to space limitations and/or environmental considerations. Public transit may deal with part of this problem; it will not have the annoying parking problems. However, a disadvantage is that public transit limits the freedom of choice of when and where to go, which is of much significance to recreational travels. Still, public transit can play a more important role in recreational travel if it is combined with cars. "Park & ride" service is an option, which is particularly useful in the densely traveled corridors between urban regions and major recreation attractions.

Benefits and Risks

Social and Economic Benefits

Donnelly and Coakley (2002) conclude the positive effects of recreation on social inclusion. Recreational travel and activity offer face-to-face contact/interaction with others and ensure that individuals have opportunities to identify common interests as well as chances to have fun together. In addition, recreational travel and activity can play a significant role in local urban economies (US National Recreation and Park Association, 2018). They contribute to economic prosperity in that related agencies employ hundreds of thousands of people and their operations and capital spending create considerable economic activities.

Health and Well-Being

There are clear evidences confirming the connections between recreation and positive health outcomes (Godbey, 2009). For example, walking, a common travel mode of recreational trips, is associated with a lower risk of heart disease, managing weight, boosting good cholesterol, preventing depression, elevating overall mood, and sense of well-being (Colditz et al., 1997). Stress reduction seems to be another major benefit: negative moods decrease after recreation, and recreationists report lower levels of sadness and anxiety during recreational travel and activity (Godbey et al., 1992). Grahn and Stigsdotter (2003) noted significant relationships between stress reduction and the visits of urban green spaces; the more often an individual visits urban green spaces, the less often he or she reports self-perceived illness. This result is applicable to the entire population, regardless of respondents' gender, age, or socioeconomic status. Moreover, De Vos (2019) concluded that the experience of leisure/recreational travel—the mood during travel and the evaluation of the trip—could contribute to one's life satisfaction.

Environmental Impacts

Automobiles are of growing importance in urban recreational travel, contributing to the increased car ownership/use and greenhouse gas emissions. Over the last decade 2005–15, the number of passenger cars (per 1000 inhabitants) in the world has grown by 20% (Eurostat, 2018). By far the fastest growth in the ratio of passenger cars to population was recorded in China, as this ratio was more than 6 times as high as in 2015 (around 100 passenger cars for every 1000 inhabitants) as in 2005. However, North America and the European Union continued to outpace most other regions in the world regarding the density of car ownership. Ownership of passenger cars in Canada was more than 600 passenger cars per 1000 inhabitants in 2015 while the EU had a density of 500.

Traffic congestion resulting from participation in recreational activities such as concerts, festivals, and sporting events is a frequent occurrence in many cities. The 2017 US NHTS shows that recreational (including social) trips account for 30% of all urban discretionary trips on weekdays. This percentage increases to around 32% on weekends when more recreational trips are performed. The NHTS also shows that (social and) recreational trips account for a substantial 27% of annual person miles of travel in the United States; this figure is 29% for New Zealand (Witten and Mavoa, 2011). Given that recreational trips are mainly made by means of car in many countries, urban recreational travel contributes a great deal to the number of passenger vehicle miles of travel on urban streets today. For instance, the NHTS data show that the annual vehicle miles of travel for recreation are 4825.5 miles (7765.9 km), 65% higher than the annual vehicle miles of travel for shopping. This contribution is only likely to get larger in the future given that disposable income and leisure time continue to grow, and as the sociodemographic characteristics of the population change over time (Misra and Bhat, 2000).

ICT and Recreational Travels

In the era of mobile Internet, the growing use of information and communication technology (ICT) has profound impacts on recreational travel. Three types of effects could be identified: substitution, generation, and modification (for a review, see Mokhtarian et al., 2006).

Substitution

ICT may provide an alternative means to perform recreational activities. If ICT-based forms of activities are chosen over location-based forms, travel is expected to be reduced. The degree of location- and time-independence of activities may impact the likelihood of being replaced by ICT-based forms. Location- and/or time-dependent activities are less likely to be substituted by ICT. Some activities are spatial-fixed (e.g., camping/backpacking or mountain climbing) or temporal-fixed (e.g., family visits on certain holidays), and hence not readily be affected by ICT. Other activities, such as playing cards and watching movies, are location- and time-independent, which makes them more likely to be influenced by ICT.

ICT may also generate new activities, for example, watching movies on the Internet. If people spend more time on ICT-based activities, it is likely that they spend less time on non-ICT-based activities (Nie et al., 2002). Even though the displacement effect could be conscious and prompt, it might also happen subconsciously and over longer time. Due to the fact that the abandoned recreational activities involve travel, this effect might also reduce travel.

Generation

Rose et al. (2009) argue that ICT is not a reasonable replacement for recreational travel since face-to-face interactions with family and friends are essential. In contrast, the use of ICT facilitates activity and travel generation (Adams, 2005; Miller, 2006). For instance, the Internet allows a last-minute reservation that was not easy previously. By providing readily available information about a variety of activity and travel options, ICT prompts making the arrangements for recreational trips. On the other hand, ICT might reduce the time and/or cost required to perform a certain activity and associated travel, with the saved time or cost used for conducting other activities. For example, the travel time saved by videoconference might be spent on recreational activities. The money saved by group buying may be spent on other recreational activities. If the new activities involve longer travels, the reallocated time to other activities derives more demand for travels.

Modification

The impact of ICT on travel might also be modification in some cases. For example, a mobile phone call is likely to change the planned travel route, and its consequences for travel distance, timing, and duration. ICT also has direct influences on travel behavior of other individuals, including generation and reduction effects. For example, arranging a social activity on the fly would not have occurred without the mobile phone (generation); mobile navigation system helps to avoid congested road (reduction).

Introduction

During the course of our lives we all develop various likes and dislikes. We develop favorite movies, foods, colors, and beaches, ski resorts, and hikes. We can have favorite material possessions, favorite relationships or people, and favorite places! On the other hand, we also develop adverse reactions to places, artifacts, and people we do not like. In the process of developing favorites, not so favorites, and the in-betweens, each person uses his or her experiences with the place, artifact, or person in question. When faced with a choice, humans consider the options, their attributes, and a variety of other factors to arrive at a decision. We name all these factors motivations along similar strands of thinking as in [Mokhtarian et al. \(2015\)](#), in other travel behavior literature. Among these motivations are the attitudes and preferences that have been formed about the choice at hand as well as other attitudes that may not be strictly related to the object of the choice ([Wang, 2015](#)). Here we focus on how we perceive places and how these perceptions correlate with how we travel.

More recent advances in travel behavior modeling and simulation have greatly increased our ability to successfully understand, analyze, and predict travel behavior as the derived demand for activity participation. This approach is dubbed the activity-based approach to travel demand forecasting ([Axhausen and Gärling, 1992](#); [Bhat and Koppelman, 1999](#); [Ettema and Timmermans, 1997](#); [Kitamura, 1988](#)). Activities are pursued in locations, and they are strongly correlated with the types of land uses at these locations, creating the necessity to integrate land use patterns with travel behavior ([Goulias, 1996](#); [Timmermans, 2003](#)). Analytical advancements have also increased the accuracy and reliability of prediction and simulation efforts and offer new opportunities to incorporate previously unmeasured behavioral determinants. These include integration of latent constructs in discrete choice methods ([Ben-Akiva et al., 2002](#)), enriching traditional models with personality indicators ([Goulias and Henson, 2006](#); [Prevedouros, 1992](#); [Steg et al., 2001](#)), account for social networks ([Arentze and Timmermans, 2008](#); [Carrasco and Miller, 2006](#)), incorporate activity scheduling and planning intentions ([Auld et al., 2008](#); [Ruiz and Roorda, 2008](#)), expanding the envelope of modeling behavior in hierarchies of lifestyles ([Van Acker et al., 2014](#)), and accounting for subjective well-being ([Mokhtarian, 2019](#); [Wang and Wang, 2016](#)). Attitudinal variables can enhance the explanatory power of behavioral models and are correlated with urban design ([Kitamura et al., 1997](#)). Moreover, spatial perception and perceived attributes are recognized as an important factor in understanding travel behavior ([Adamowicz et al., 1997](#); [Ahuja et al., 2018](#); [Goulias et al., 1998](#); [Golledge and Garling, 2003](#); [Hoehner et al., 2005](#)). Evidence is also increasing about the need to combine built environment metrics with psycho-attitudinal metrics about places and perceptions of the environment ([Clifton and Perez, 2015](#); [Hannes et al., 2012](#)).

Space, Place, Scale, and Sense of Place

In this chapter we distinguish between space and place following a typical geographic definition that defines place as a qualified space with distinct spatial attributes. With this in mind, travel behavior analysis has modeled the influence of places on behavior using measured spatial attributes such as accessibility and access to facilities ([Geurs and Van Wee, 2004](#); [Handy and Niemeier, 1997](#)). These spatial attributes are summarized in indicators that include the attractive features of a place and the difficulty to reach them ([de Abreu et al., 2012](#); [Lin et al., 2014](#)). These metrics are then used to define attractiveness of a place as explanatory variables of daily behavior. In activity-based models we often use availability of opportunities for different types of places including travel time by different modes to reach opportunities and time of day availability of these opportunities ([Chen et al., 2011](#)). Individuals' perceptions of places reflect these measurable attributes of places, as a starting point for making destination choice models that better reflect human spatial decision making ([Pike and Ryan, 2004](#), and a chapter in this encyclopedia). This is not enough to understand behavior because people perceive attributes of these locations in different ways and because they attribute meanings to places that change in their life course. The nature of the meanings assigned to places is still debated ([Agarwal, 2018](#)). However, a

group of meanings in the form of attitudes (beliefs coupled with affective stances) have been tested as a summary of these meanings and named *Sense of Place*. The term *Sense of Place* (also defined as the powerful connection between people and places or the affective ties of people with places) has a long history in human geography, and the theory generally operates in realms that are deeply personal and social but invisible. Numerous efforts to pin down specific aspects of places are found in the geography and environmental psychology literature (Proshansky, 1978; Stedman, 2003; Stokols and Shumaker, 1981). Similarly, in the tourism research literature one aspect of *Sense of Place* called place image is used for marketing destinations (Campelo et al., 2014; Chon, 1990; Elliot et al., 2011) and recognize the importance of correlating tourists and residents *Sense of Place* for design of destinations (Kianicka et al., 2006; Styliadis et al., 2016).

Quantifying *Sense of Place* with the specific goal to include it as a determinant of daily travel behavior can be done through the use of attitudinal questions in human surveys and examination of their correlation with travel behavior (Chen and Sekar, 2018; Deutsch and Goulias, 2010). This quantified sense of place can also be used in land use policy implementation to identify resistance to change due to *Sense of Place* but also to design and improve urban design quality (Hu and Chen, 2018). A place can be a house, a store, a neighborhood, a section of a city, or even an entire region or country making quantification of sense of place and the formation of metrics scale dependent (Montello, 1993). *Sense of Place* is generally only studied for particularly meaningful places like the home, but studying place at broader scales can greatly expand our understanding of people's day-to-day activities outside the home. In translating quantified *Sense of Place* to policies we also need to develop metrics at the appropriate scale. In this chapter we review quantification of place perception and *Sense of Place* at two different scales.

Quantifying Sense of Place for Centers of Activity

Quantification of sense of place was done in a Santa Barbara, CA, experiment using 719 persons from an intercept survey conducted at two outdoor shopping centers (malls). Both malls are situated along one of Santa Barbara's main arterial streets, State Street, one being downtown (Paseo Nuevo) and one uptown (La Cumbre). At the time of the study, both malls offered two anchor big box stores, and a variety of smaller retail stores. In addition, both places offer restaurants and additional nearby shopping. Details of the study areas and data collection process and instrument are discussed in Deutsch and Goulias (2010). The survey consisted of questions developed to capture the respondents' sense of place views toward each mall. Following work conducted by Jorgensen and Stedman (2001) and Stedman (2003) in environmental psychology a series of questions were adapted to this study which were focused on the respondents' place attachment, place identity, and place dependence. In addition, several additional questions were included to examine other aspects of sense of place. All sense of place questions used a seven-point Likert scale, ranging from strongly disagree to strongly agree. Additionally, several socioeconomic and demographic questions were included as well as questions about travel behavior before, during, and after the visit to the shopping mall to capture the role of visiting a specific place in the context of daily behavior. Because of the intercept format of the survey, travel behavior variables are limited to a small snapshot of the day's activities. In this work, we found that three additional constructs create a more complete sense of place representation, which are correlated with individual characteristics and travel behavior indicators (Fig. 1). The additional constructs are based on questions relating to one's satisfaction with the place, a construct of sense of place previously developed but not as widely known (Stedman, 2003), as well as questions about the physical/aesthetic surroundings of the place and the social environment. Researchers have discussed the importance of physical, social, and cultural attributes of place in developing a sense of place (Stokols and Shumaker, 1981). The inclusion of these indicators in a factor analysis provides insight into how these concepts manifest themselves in everyday activity locations, and which place attributes are more apparent in everyday settings. In this example six factors (attachment, dependence, identity, satisfaction, atmosphere, and community) represent sense of place. Each factor is measured by three to six indicators (answers to the attitudinal questions), and the factors are explained by sociodemographic variables and characteristics of the day. In this comparison between two shopping malls in Santa Barbara we also find that: (1) places with similar affordances have different sense of place meaning to patrons; (2) different travel behavior facets are influenced in different ways by sense of place; and (3) sociodemographics are correlated the *Sense of Place* factors, but they are not able to exhaustively map differences among people and therefore cannot substitute sense of place metrics. Different socio-demographic factors influence sense of place at the two sites. For example, marital status and income are important factors at Paseo Nuevo, as are gender and marital status at La Cumbre. For both sites, important explanatory variables include income, age, gender, ethnicity, and ownership of a bus pass and possession of a driver's license. Several *Sense of Place* indicators influence travel behavior variables. Of note, the use of a car is associated with lower place dependence and satisfaction, but a higher place identity. Additionally, walking is associated with high ranking of a place's atmosphere. However, causality should not be inferred in this case—Do those who have a positive view of the atmosphere choose to walk, or do those who walk take notice and view the surrounding atmosphere more positively? Additionally, walkers have a lower attachment score. Atmosphere was again significant for those who have no companion in their visit to the mall. The model diagram in Fig. 1 shows that persons of different gender and ethnicity and at different stages of their life cycle (e.g., having children) also have different sense of place attitudes. It also shows that these same attitudes are different depending on the day of the week and time of day presumably due to the different roles places play in peoples' schedule of activities in a week and within a day. Similar influence of day of the week and time of day is also found for sequencing of activities (see the dashed line to the left hand side of the figure). Sense of place is a dynamic concept that changes within a day, within a week, and within a life course. This makes it hard to measure and at the same time is a rich informant of behavior. In a subsequent study Chen and Sekar (2018) used the same six *Sense of Place* factors to study the frequency of visiting places and nonmotorized mode choice for

Figure 1 Conceptual and correlational sense of place diagram.

Figure 2 Attractiveness, danger, opportunities, familiarity, and a composite attractiveness index for Santa Barbara hexagons.

three sites in Rochester, NY, proving repeatability of this technique of behavioral measurement. They also studied the use of information and communication technology (ICT) about the three sites. In terms of the relationship between *Sense of Place* and travel behavior they found *Sense of Place* influencing the propensity of people not only to visit places more often, but also to use nonmotorized modes. In addition, getting information about places via ICT changes peoples *Sense of Place*.

Quantifying Citywide Sense of Place

The primary tool to link citywide land use with transportation services and travel behavior is accessibility through a metric representing the ease of reaching opportunities, amenities, and services (Geurs and Van Wee, 2004; Handy and Niemeier, 1997). Distinguishing between experienced accessibility versus objectively measured accessibility is the subject of more recent studies that use travel behavior data to inform place perception (Thériault and Des Rosiers, 2004). Similarly, comparisons between perceived and objectively measured mode-specific attributes are also used to link propensity of using modes and place-specific risks (Manton et al., 2016). These are methods that measure perception of place affordances and represents one dimension of place quality. In contrast, one can quantify *Sense of Place* citywide using attitudinal questions about each location in a city and develop maps of cities that capture not only perceptions of affordances but also feelings, emotions, and place-specific perceptions of quality of life.

In a pilot study in South Santa Barbara County, CA, a direct measurement of place perceptions was implemented as a mapping exercise dividing the study area in 23 hexagons (tessellating the study region) asking respondents to rank their agreement on a Likert-like scale (of -3 being strongly disagree to +3 being strongly agree), with respect to four descriptive questions. The number of hexagons tessellating the study area as well as the number of questions used to capture place perception requires deliberate thought and attention to the balance between level of detail of the data and respondent burden. The four key questions (as well as their keywords in parentheses) for each hexagon are: (1) this is an attractive area of Santa Barbara (attractiveness); (2) this is a dangerous area of Santa Barbara (perception of danger); (3) this area provides me with a lot of opportunities to do things I like to do (opportunities); (4) I am very familiar with this area of Santa Barbara (familiarity). These attributes combine a variety of discussions on topics such as the development of cognitive maps and the influence of the physical landscape on psychological perspectives and human spatial interaction. Attractiveness of the landscape can be seen as an element that contributes to cognitive aspects such as the legibility of places (Lynch, 1960), development of sense of place (Bjørn and Bjerke, 2002), differences that exist between perception and reality of danger (Rengert and Pelfrey, 1997); and the role of exposure to the region as a factor of attaching meaning of places and organizing mental representations of spatial information (Golledge and Spector, 1978; Portugali, 2018).

Following this mapping exercise, respondents were also asked to score the importance of each of these four aspects when choosing a destination for an activity on a 1 through 10 scale (with 1 being not important, and 10 being very important). A full description of the methodology and reasoning behind the use of this hexagonal method can be found in (Deutsch, 2013). Based on

the respondent data an index of subjective attractiveness for each hexagon was created that in essence is the sum of importance by perception of each of the four questions and the weight or importance that individual gives to each aspect of place (Fig. 2). Attractiveness and opportunities were thought to be attractors and therefore were given positive influence in the place equation, danger was seen as a negative, and therefore had a negative influence, and familiarity was determined to magnify these perceptions and therefore was treated as a multiplier of the three aforementioned indicators (other types of indices are documented in Deutsch (2013). Deutsch-Burgner and Goulias (2015)). Our team also used latent class cluster analysis on these data and found noticeable differences among attractiveness of the hexagons. Residents of the Eastern side of town (Montecito and Downtown/midtown region) had higher geographic preference toward the downtown and Montecito areas. Goleta residents (the western portion of the study region) however were less geographically biased and more consistent with indicators of attraction based on density of opportunities (the downtown area). All this supports the use of subjective measures of accessibility in models to improve realism.

Subjective well-being is a more recent interest in travel behavior research (Mokhtarian, 2019) and in the wider regional science research (Ballas and Tranmer, 2012). Deutsch et al. (2013, 2014) and Deutsch and Goulias (2013) examined the attractiveness of the hexagons and their relationship with subjective well-being and happiness jointly with other characteristics. In this portion of the survey, participants rated how different aspects matter to them in the selection of a destination for grocery shopping, other shopping, activities with family, outdoor recreation, social activities, eating out, and entertainment. The questions iterated through each of the seven activity types, and responses were on a seven point Likert scale from strongly disagree to strongly agree. The attributes include: (1) cost of goods or services at the place—"cost"; (2) whether the place is a good reflection of the type of person I am—"identity"; (3) the quality of the products or services offered—"quality"; (4) Whether the place has a positive social atmosphere—"social"; (5) how much time it will take me to travel to the place—"travel time"; (6) how well the place reflects the Santa Barbara lifestyle—"culture"; (7) how close the place is to my home—"distance"; (8) the safety of the surrounding area—"safe"; (9) if there are other places close by where I can do other activities—"proximity"; (10) whether the place meets all my (fill in the activity type) needs—"dependence"; (11) whether the place makes me feel happy—"happy".. Analysis of these aspects shows that individuals have different expectations and criteria to evaluate a destination, and therefore the activities at each place. For instance, happiness matters less for shopping activities than it does for family, social or recreation activities. Additionally, proximity is consistently ranked in the middle of all aspects of place, which challenges current practices of modeling accessibility as one of the most important factors in choosing one destination over another. It also shows that sense of place indicators as stronger than the usual cost and time variables to explain preferences. Moreover, anticipated subjective well-being is a motivator for activity location choice.

To test further these findings, Davis (2015) and Davis et al. (2015) also studied the correlation between attitudes measured with this hexagonal tessellation with objectively measured spatial opportunities (enumeration of business establishments by type) and online reports on Twitter (see the sentiment review by Hollander et al., 2016). They found that the opportunities people believe a place provides are higher when business establishments are more numerous, areas that provide more natural amenities are considered more attractive, and area residents are generally more familiar with areas that are more attractive and opportunity-rich. This portion of comparison with Twitter data shows that online social media provide a different facet of place attitudes with a rich vocabulary of positive and negative aspects of different places that are not readily translatable to travel behavior variables.

Closing Remarks

In summary, place perceptions have a strong influence on decision making and choices in travel behavior such as the choice of a destination. The development of place perceptions, or *Sense of Place*, is a function of individual preferences as well as a variety of elements of the physical, social, and cultural environment of a place. Place perceptions are important to recognize in our attempts to understand, measure, model, and predict travel behavior using quantitative measures of *Sense of Place*. In this way the more traditional attributes of distance, cost or time, and summaries of affordances such as accessibility can be complemented by a variety of subjective measures of place attractiveness and their decision making weights.

The examples presented here are a small portion of the rich body of literature describing and theorizing the interaction of people and place and the affective ties that one develops. The examples here show how measurement can be done at different scales applying *Sense of Place* concepts to the measurement of everyday locations and the application in travel behavior shows modeling is possible and beneficial as a multiscale process. The *Sense of Place* development and analysis described here suggests that *attachment, dependence, identity, satisfaction, atmosphere and community* are the six most important factors for small-scale application. For larger scales perceptions of opportunities and attractiveness combined with perception of danger and familiarity can be used as succinct summaries of place perception. These cannot be indirectly measured by other variables or represented using socio-demographics due to heterogeneity of perception among people.

As we have discussed, place perceptions influence the production and generation of travel and as such they are therefore integral to include in urban design efforts. As we strive to design for all modes of transportation, it is important to include design elements that influence the use of those modes. Lighting, inviting open spaces or storefronts, and vegetation, benches or other street furniture can all contribute to a positive development of atmosphere perceptions and therefore *Sense of Place*. Elements of place perceptions should therefore be included in metrics we use to design complete streets (streets that enable the use of all modes comfortably, equitably, and safely, Hui et al., 2018). Beyond the complete streets idea, Hu and Chen (2018) present a framework for integrating landscape design with place perceptions in order to create urban environments that foster positive

places. This should extend to the prescriptions of human-centered landscape architecture that appeals to the physiological aspects of every-day life (Gehl, 2011, 2013). Combining place perceptions with traditional design standards and metrics can enhance the environment, *Sense of Place*, and therefore quality of life of people who dwell or frequent these urban environments.

INTRODUCTION

Roger Vickerman

In an increasingly globalized world, despite reductions in costs and time, transportation has become even more important as a facilitator of economic and human interaction; this is reflected in technical advances in transportation systems, increasing interest in how transportation interacts with society and the need to provide novel approaches to understand its impacts. This has become particularly acute with the impact that Covid-19 has had on transportation across the world, at local, national, and international levels. This Encyclopedia brings a cross-cutting and integrated approach to all aspects of transportation from work in many disciplinary fields, engineering, operations research, economics, geography, and sociology to understand the changes taking place.

Transportation is both influenced by, and an influencer of, changes in the economy and society. Increasing speeds have reduced journey times and made the world a smaller place as globalization has affected both where people live and work and from where they source their goods and materials. Increasing volumes of traffic, often on old and life-expired infrastructure, lead to congestion and delays. Constraints on public budgets have led to increasing pressure on the private sector to fund improvements requiring new and innovative financial solutions. While there are clear differences in the nature of the pressures felt in the developed and less developed economies, there is an increasing recognition that in all societies, there is an accessibility problem such that certain groups become disadvantaged by the lack of access to reliable and cost-effective transport. While the problems are clearly multidimensional, research on transportation is often constrained by single disciplinary approaches and this carries over into the practice of transport planning and policy. The Encyclopedia cuts across these artificial boundaries by taking an approach that emphasizes the interaction between the different aspects of research and aims to offer new solutions to understand these problems. Each of the nine sections is based around a familiar dimension of work on transportation, but brings together the views of experts from different disciplinary perspectives. Each section is edited by an expert in the relevant field who has sought chapters from a range of authors representing different disciplines, different parts of the world, and different social perspectives. In this way, the work is not just a reflection of the state of the art that serves as a starting point for researchers and practitioners, but also a pointer toward new approaches, new ways of thinking, and novel solutions to problems.

The nine sections are structured around the following themes: Transport Modes; Freight Transport and Logistics; Transport Safety and Security; Transport Economics; Traffic Management; Transport Modeling and Data Management; Transport Policy and Planning; Transport Psychology; Sustainability and Health Issues in Transportation. Some of the chapters provide a technical introduction to a topic while others provide a bridge between topics or a more future-oriented view of new research areas or challenges. While there is guidance to cross-referencing between chapters, readers are encouraged to explore the tables of contents of all the sections to get a full understanding of the issues. Much of the Encyclopedia was completed before the Covid-19 pandemic and clearly this will have changed the situation in many areas covered by this work; the advantage of this type of reference work is that relevant updates will be possible in future editions.

The Encyclopedia has only been possible because of the cooperation of a large number of people. Robert Noland, Georgina Santos, Xiaowen Fu, and Dick Ettema served as an Editorial Advisory Board identifying possible editors of sections and advising on the overall structure. The Section Editors, Edoardo Marcucci, Kevin Cullinane, Per Garder, Maria Börjesson, Edward Chung, Chandra Bhat, Maria Attard, and Carlo Prato,

carried out the work of identifying potential authors of individual chapters, commissioning these, encouraging authors and reviewing drafts. More than 600 authors and co-authors of chapters are, however, ultimately responsible for the success of this venture. Thanks are also due to the key people at Elsevier, particularly the Publishers, Andre Wolff and Oliver Walter, and the Project Managers, Sophie Harrison and Natalie Bentahar; they have shown exemplary patience over more than 3 years in bringing this work to fruition.

LIST OF CONTRIBUTORS TO VOLUME 5

Edoardo Marcucci

Department of Political Sciences, University of Roma Tre, Rome, Italy; Department of Logistics, Molde University College, Molde, Norway

Xavier Fageda

Department of Applied Economics and GIM-IREA, Universitat de Barcelona, Barcelona, Spain

Cecilia Olivieri

Department of Economics, Faculty of Social Sciences, Universidad de la República, Montevideo, Uruguay

Charles B.A. Musselwhite

Centre for Innovative Ageing, Swansea University, Swansea, United Kingdom

Theresa Scott

University of Queensland, St. Lucia, QLD, Australia

Erling Holden

Faculty of Environmental Sciences and Natural Resource Management, Norwegian University of Life Sciences, Aas, Norway

Geoffrey Gilpin

Department of Environmental Sciences, Western Norway University of Applied Sciences, Sogndal, Norway

Michele D. Simoni

Department of Civil, Architectural, and Environmental Engineering, The University of Texas at Austin, Austin, TX, United States

Kara M. Kockelman

Center for Transportation and Logistics, Massachusetts Institute of Technology, Cambridge, MA, United States

Ila Maltese

Dipartimento di Scienze Politiche, Università degli Studi Roma3, Roma, Italy

Luca Zamparini

Dipartimento di Scienze Giuridiche, University del Salento, Lecce, Italy

Bert van Wee

Delft University of Technology, Delft, The Netherlands

Jean-Paul Rodrigue

Department of Global Studies and Geography, Hofstra University, Hempstead, NY, United States

Erick Guerra

University of Pennsylvania, Stuart Weitzman School of Design, Department of City and Regional Planning, Philadelphia, PA United States

Gilles Duranton

University of Pennsylvania, The Wharton School, Real Estate Department

Lóránt Tavasszya

Delft University of Technology, Delft, The Netherlands

Gerard de Jongb

Institute for Transport Studies, University of Leeds, United Kingdom and Significance, The Hague, The Netherlands

Sebastian Bamberg

Department of Social Sciences, University of Applied Sciences, Bielefeld, North Rhine-Westphalia, Germany

Icek Ajzen

Department of Psychological and Brain Sciences, University of Massachusetts Amherst, Amherst, MA, United States

Peter Schmidt

Department of Political Science and Centre for Environment and Development (ZEU), University of Giessen, Ludwigstrasse, Germany

Zissis Samaras

Department of Mechanical Engineering, Aristotle University of Thessaloniki, Greece

Ilias Vouitsis

Department of Mechanical Engineering, Aristotle University of Thessaloniki, Greece

CONTENTS OF ALL VOLUMES

<i>Editorial Board</i>	<i>v</i>
<i>Introduction</i>	<i>vii</i>
<i>Contributors to Volume 5</i>	<i>ix</i>

VOLUME 1

Introduction to Transportation Economics	1
Market Failures and Public Decision Making in the Transport Sector <i>Bruno De Borger and Stef Proost</i>	2
Demand for Freight Transport <i>José Holguín-Veras and Diana G. Ramírez-Ríos</i>	7
Cost Functions for Road Transport <i>José Manuel Vassallo</i>	13
Future of Urban Freight <i>Russell G. Thompson</i>	20
Operation Costs for Public Transport <i>Marco Batarce</i>	26
Natural Monopoly in Transport <i>André de Palma and Julien Monardo</i>	30
Freight Costs: Air and Sea <i>Yulai Wan and Dong Yang</i>	36
Transport Production and Cost Structure <i>Ricardo Giesen and Darío Farren</i>	46
The Concept of External Cost: Marginal versus Total Cost and Internalization <i>Sofia F. Franco</i>	56
Value of Time <i>John J. Bates</i>	67
Valuation of Carbon Emissions <i>Svante Mandell</i>	72
Valuation of Travel Time Variability Using Scheduling Models <i>Katrine Hjorth</i>	76

Value of Crowding <i>Daniel Hörcher</i>	84
What Drives Transport and Mobility Trends? The Chicken-and-Egg Problem <i>Nathalie Picard</i>	89
Pricing Principles in the Transport Sector <i>Bruno De Borger and Stef Proost</i>	95
Long-Run Versus Short-Run Valuations <i>Stefanie Peer</i>	102
Value of Noise <i>Jon P. Nelson</i>	106
The Value of Life and Health <i>Henrik Andersson</i>	114
The Value of Security, Access Time, Waiting Time, and Transfers in Public Transport <i>Raquel Espino, Juan de Dios Ortúzar, and Luis I. Rizzi</i>	122
Demand for Passenger Transportation <i>Kenneth A Small and Robin Lindsey</i>	127
Real-World Experiences of Congestion Pricing <i>Charles Raux</i>	134
Distributional Effects of Congestion Charges and Fuel Taxes <i>Jonas Eliasson</i>	139
The Bottleneck Model <i>Dereje Abegaz and Yili Tang</i>	146
Dynamic Congestion Pricing and User Heterogeneity <i>Kathrin Goldmann and Gernot Sieg</i>	150
Economics of Parking <i>Daniel Albalade and Albert Gragera</i>	159
Loss Aversion and Size and Sign Effects in Value of Time Studies <i>Andrew Daly</i>	165
Intertemporal Variation of Valuations <i>James Fox</i>	170
The Rebound Effect for Car Transport <i>Bruno De Borger, Ismir Mulalic and Jan Rouwendal</i>	174
Elasticities for Travel Demand: Recent Evidence <i>Fay Dunkerley, Charlene Rohr and Mark Wardman</i>	179
Parking Price Elasticities <i>Stephan Lehner</i>	185
The Pareto Criterion and the Kaldor Hicks Criterion <i>Harald Minken</i>	190
Social Discount Rates <i>Lars Hultkrantz</i>	195
Cross-Elasticities between Modes <i>Mark Wardman and Jeremy Toner</i>	201
First-Best Congestion Pricing <i>Moez Kilani</i>	209

Ethical Aspects-Can We Value Life, Health, and Environment in Money Terms? <i>Jose M. Grisolia and Ken Willis</i>	216
Car tolls, Transit Subsidies for Commuting, and Distortions on the Labor Market <i>Ioannis Tikoudis¹ and Kurt Van Dender¹</i>	221
Demand Management and Capacity Planning of Airports <i>Stephen Ison and Lucy Budd</i>	227
Dealing With Negative Externalities: Low Emission Zones Versus Congestion Tolls <i>Valeria Bernardo, Xavier Fageda, and Ricardo Flores-Fillol</i>	231
The Rule-of-a-Half and Interpreting the Consumer Surplus as Accessibility <i>Mogens Fosgerau and Ninette Pilegaard</i>	237
Producer Surplus <i>Chau Man Fung</i>	242
The Robustness of Cost-Benefit Analyses <i>Morten Welde and James Odeck</i>	249
The GDP Effects of Transport Investments: The Macroeconomic Approach <i>James Laird and Daniel Johnson</i>	256
The Mohring Effect <i>Hugo E. Silva</i>	263
Public Transport Fare and Subsidy Optimization <i>Qianwen Guo and Zhongfei Li</i>	267
Transportation Equity <i>Rafael H. M. Pereira, and Alex Karner</i>	271
Impact of Transport Cost-Benefit Analysis on Public Decision-Making <i>Niek Mouter</i>	278
Causal Inference for Ex Post Evaluation of Transport Interventions <i>Daniel J. Graham</i>	283
Transport Cost and Location of Firms <i>Adelheid Holl</i>	291
Commuting, the Labor Market, and Wages <i>Jan Rouwendal, and Ismir Mulalic</i>	297
How to Buy Transport Infrastructure <i>Johan Nyström</i>	302
Procurement of Public Transport: Contractual Regimes <i>Andrew Smith, and Chris Nash</i>	308
The Mono-Centric City Model and Commuting Cost <i>Zhi-Chun Li, and Ya-Juan Chen</i>	315
Value of Time in Freight Transport <i>Gerard de Jong</i>	321
The Economics and Planning of Urban Freight Transport <i>Edoardo Marcucci, Valerio Gatta, and Michela Le Pira</i>	326
Incentives in Public Transport Contracts <i>Andreas Vigren</i>	332
Transportation Improvements and Property Prices <i>Alex Anas</i>	337

Transport Infrastructure Effects on Economic Output: The Microeconomic Approach <i>Patricia C. Melo</i>	347
Wider Economic Impacts of Transport Investments <i>Anthony J. Venables</i>	355
Employment Effects of Transport Infrastructure <i>Anna Matas, and Javier Asensio</i>	360
Regulatory Reforms and Competition in Public Transport <i>Didier van de Velde</i>	365
How to Finance Transport Infrastructure? <i>Tiziana D'Alfonso, and Giuseppe Catalano</i>	371
Congestion, Allocation and Competition on the Railway Tracks <i>John Armstrong, and John Preston</i>	378
Public Private Partnership <i>David Meunier, and Emile Quinet</i>	385
Airline Economics <i>Anming Zhang, Yahua Zhang, and Zhibin Huang</i>	392
Privatization and Deregulation of the Airline Industry <i>Achim I. Czerny, and Hao Lang</i>	397
Price Discrimination and Yield Management in the Airline Industry <i>Guoquan Zhang, Colin C.H. Law, Yahua Zhang, and Hangjun Yang</i>	404
Regulation and Competition in Railways <i>Chris Nash, and Andrew Smith</i>	409
Cycling Economics <i>Bert van Wee</i>	414
The Economic Rationale for High-Speed Rail <i>Ginés de Rus</i>	419
Rail Cost Functions <i>Kristofer Odolinski, and Phill Wheat</i>	425
Transport and International Trade <i>Siri Pettersen Strandenes</i>	431
Maritime Economics: Organizational Structures <i>Kevin P.B. Cullinane</i>	436
Port Planning and Investment <i>Jasmine Siu Lee Lam</i>	443
Estimating the Capital Stock of Transport Infrastructure <i>Heike Link</i>	449
The Economics of Reducing Carbon Emissions From Air and Road Transport <i>Olga Ivanova</i>	457
Regulation and Financing of Toll Roads <i>Marco Ponti</i>	464
Are Megaprojects too Transformational for Cost-Benefit Analysis? <i>Tom Worsley</i>	470
Economics of Transportation Safety <i>Ian Savage</i>	476

Cost Overruns of Transportation Infrastructure Projects <i>James Odeck, and Morten Welde</i>	483
The Downs-Thomson Paradox <i>Joel P. Franklin</i>	490
Policy Instruments for Plug-In Electric Vehicles: An Overview and Discussion <i>Jake Whitehead, Patrick Plötz, Patrick Jochem, Frances Sprei, and Elisabeth Dütschke</i>	496
Vertical and Horizontal Separation in the European Railway Sector and Its Effects on Productivity <i>Pedro Cantos-Sánchez</i>	503
How will Autonomous Vehicles Impact Car Ownership and Travel Behavior <i>Patrick M. Bösch, Felix Becker, Henrik Becker, and Kay W. Axhausen</i>	508
Policy Instruments to Reduce Carbon Emissions from Road Transport Computable General Equilibrium Analysis in Transportation Economics <i>Johannes Bröcker</i>	520
Estimation of Value of Time <i>Stefan Flügel, and Askill H. Halse</i>	527
The Taxation of Car Use in the Future <i>Griet De Ceuster, and Inge Mayeres</i>	534
Cost-Benefit Analysis and Other Assessment Techniques: Contrasts and Synergies <i>Paolo Beria</i>	540
Demand for Air Travel and Income Elasticity <i>Jing Lu, Yucan Meng, Changmin Jiang, and Cheng Lv</i>	547
Generalized Cost for Transport <i>Jepppe Rich</i>	555
The Impact of Electric Vehicles on Energy Systems <i>Patrick E.P. Jochem, Jake Whitehead, and Elisabeth Dütschke</i>	560
Uber versus Taxis <i>Georgina Santos</i>	566
Contract Efficiency in Public Transport Services <i>Philippe Gagnepain, and Marc Ivaldi</i>	572
Company Cars <i>Stefan Gössling</i>	580
Transportation Network Companies (TNCs) and the Future of Public Transportation <i>Susan Shaheen, and Adam Cohen</i>	584
Public Transport in Low Density Areas <i>Jani-Pekka Jokinen, Leif Sörensen, and Jan Schlüter</i>	589
Market Failures in Transport: Direct and Indirect Public Intervention <i>Federico Boffa, and Alberto Iozzi</i>	596
The Braess Paradox <i>Anna Nagurney, and Ladimer S. Nagurney</i>	601
VOLUME 2

VOLUME 5

Transport Modes <i>Edoardo Marcucci</i>	1
Infrastructure Transport Investments, Economic Growth and Regional Convergence <i>Xavier Fageda and Cecilia Olivieri</i>	2
Transport Modes and an Aging Society <i>Charles B.A. Musselwhite and Theresa Scott</i>	6
Sustainable Mobility Paths <i>Erling Holden and Geoffrey Gilpin</i>	13
Vehicles that Drive Themselves: What to Expect with Autonomous Vehicles <i>Michele D. Simoni and Kara M. Kockelman</i>	19
Transport Modes and Tourism <i>Ila Maltese and Luca Zamparini</i>	26
Transport Modes and Accessibility <i>Bert van Wee</i>	32
Transport Modes and Globalization <i>Jean-Paul Rodrigue</i>	38
Transport Modes and Cities <i>Erick Guerra and Gilles Duranton</i>	45
Transport Modes and Remote Areas	51
Modeling Mode Choice in Freight Transport <i>Lóránt Tavasszya and Gerard de Jongb</i>	57
Travel Mode Choice as Reasoned Action <i>Sebastian Bamberg, Icek Ajzen, and Peter Schmidt</i>	63
Energy Consumption of Transport Modes <i>Zissis Samaras and Ilias Vouitsis</i>	71
Transport Modes and People With Limited Mobility <i>Roger L Mackett</i>	85
Transport Modes and Commuters <i>Colin G. Pooley</i>	92
Shopping and Transport Modes <i>Antonio Comi</i>	98
Transport Modes and Health <i>Jennifer S. Mindell and Sandra Mandic</i>	106

Multimodality in Transportation <i>Sören Groth and Tobias Kuhnimhof</i>	118
Transport Modes and Disasters <i>Brian Wolshon</i>	127
Big Data for Public Transport Planning <i>Jan-Dirk Schmöcker</i>	134
Active Transport: Heterogeneous Street Users Serving Movement and Place Functions <i>Regine Gerike, Stefan Hubrich, Caroline Koszowski, Bettina Schröter, and Rico Wittwer</i>	140
Electric Vehicles <i>Christine Eisenmann, Daniel Görges, and Thomas Franke</i>	147
Shared Mobility: An Overview of Definitions, Current Practices, and Its Relationship to Mobility on Demand and Mobility as a Service <i>Susan Shaheen, PhD and Adam Cohen</i>	155
Adoption of new travel information platforms <i>Sigal Kaplan</i>	160
ICT and Transport Modes <i>Galit Cohen-Blankshtain</i>	165
Mode Choice and Life Events <i>Joachim Scheiner</i>	171
Introduction to Air Transport <i>Milan Janić</i>	178
The History of Air Transportation <i>Richard P. Hallion</i>	192
The Geography of Air Transport <i>Lucy Budd and Stephen Ison</i>	198
The Future of Air Transport <i>Rico Merkert and James Bushell</i>	203
Air Transport and Its Territorial Implications <i>Lanfranco Senn</i>	208
Next Generation Travel: Young Adults' Travel Patterns <i>Tobias Kuhnimhof and Scott Le Vine</i>	215
Airport Network Planning and Its Integration with the HSR System <i>Francesca Pagliara, Juan Carlos Martín, and Concepción Román</i>	222
Airport Management <i>Peter Forsyth and Hans-Martin Niemeier</i>	229
Airport Regulation <i>Achim I. Czerny</i>	234
Air Route Planning and Development <i>Renan Peres de Oliveira and Gui Lohmann</i>	241
Airline Management <i>Sveinn Vidar Gudmundsson</i>	249
Air Cargo <i>Volodymyr Bilotkach</i>	258

Airline Regulation <i>Andrew R. Goetz</i>	263
Air Vehicles Classification <i>Vincenzo Torre</i>	269
Aircraft Manufacturing <i>Antonio Sollo</i>	290
A Geography of Road Transport in Cities <i>Cristian Domarchi and Juan de Dios Ortúzar</i>	300
The Future of Road Transport <i>Preston L. Schiller</i>	306
Road Transportation and Territorial Scale <i>Ana M. Condeço-Melhorado</i>	315
Road Modes: Walking <i>Kevin Manaugh, PhD Associate Professor</i>	320
Bus Public Transport Planning and Operations <i>Ehab Diab and Ahmed El-Geneidy</i>	326
Street Design for Active Travel <i>Bruce Appleyard</i>	333
Transit Planning and Management <i>Zakhary Mallett and Marlon G Boarnet</i>	349
Road Infrastructure: Planning, Impact and Management <i>Jos Arts, Wim Leendertse, and Taede Tillema</i>	360
Road Transport Planning at the Urban Scale <i>David A. King and Kevin J. Krizek</i>	373
Road Traffic Regulation: Road Pricing and Environmental Quality <i>Marco Percoco</i>	378
Car Ownership and Car Use: A Psychological Perspective <i>J.L. Veldstra, A.B. Ünal, E.M. Steg</i>	384
Road Transport: E-Scooters <i>Gysele Lima Ricci and Klaus Bogenberger</i>	391
Railway Station and Network Planning <i>Ingo Arne Hansen</i>	399
Introduction to Rail Transport <i>Chris Nash and Tony Fowkes</i>	406
The History of Rail Transport <i>Carlo Ciccarelli, Andrea Giuntini, and Peter Groote</i>	413
The Geography of Rail Transport <i>Frédéric Dobruszkes and Amparo Moyano</i>	427
Rail Transport and Territorial Scale <i>Prof. Andrés Monzón and Dr. Elena López</i>	437
Railway Management <i>Vassilios A. Profillidis</i>	444
Railway Terminal Regulation <i>Nacima Baron</i>	454

Service Network Design for Freight Railroads <i>Teodor Gabriel Crainic</i>	464
Subway Systems <i>Guillaume Monchambert, Daniel Hörcher, Alejandro Tirachini, and Nicolas Coulombel</i>	471
Railway Company Management <i>Vilius Nikitinas, Skaistė Miliauskaitė</i>	479
Regulation of Rail Infrastructure and Services <i>Javier Campos</i>	485
Rail Vehicle Classification <i>Christos Pyrgidis and Alexandros Dolianitis</i>	490
Introduction to Maritime Shipping <i>Christa Sys and Thierry Vanelslander</i>	508
The Geography of Maritime Transport <i>César Ducruet and Justin Berli</i>	517
The Future of Maritime Transport <i>Harilaos N. Psaraftis</i>	535
Maritime Transport and Territorial Scale <i>Brian Slack</i>	540
Containerization and the Port Industry <i>Hercules Haralambides</i>	545
Port Management <i>Lourdes Trujillo, Daniel Castillo Hidalgo, and Manuel Herrera</i>	557
Economic and Environmental Regulation in the Port Sector <i>Beatriz Tovar and Alan Wall</i>	563
Maritime Route Planning <i>Johan Woxenius</i>	570
Inland Waterway Transport and Inland Ports: An Overview of Synchromodal Concepts, Drivers, and Success Cases in the IWW Sector <i>Behzad Behdani, Bart Wiegman, and Yun Fan</i>	577
Maritime Company Passenger Management/Liner Industry <i>Claudio Ferrari and Alessio Tei</i>	587

Transport Modes

Edoardo Marcucci, Department of Political Sciences, University of Roma Tre, Rome, Italy; Department of Logistics, Molde University College, Molde, Norway

© 2021 Elsevier Ltd. All rights reserved.

“Transport Modes” constitutes one of the nine sections composing the Encyclopedia on Transport.

Be it passenger or freight, transport takes place using different modes to move people/goods from A to B. This distinction is blurred when both passengers and freight (e.g., free luggage capacity in passenger planes is used to ship goods) jointly use the same mode. The transport modes typically considered are road, rail, air and maritime.

The distinctions among the modes relates to issues that are technical (e.g., speed, capacity), technological (e.g., ICE/Electric), operational (e.g., speed/weight limits, safety/security conditions, operating hours) and commercial (e.g., transport demand, ownership).

Mode choice and mode shift are fundamental topics to investigate since they have relevant implications for different transport--related aspects such as cost, time, reliability, frequency, punctuality, resilience, emissions and accidents. Agents' mode choice strictly correlates with other topics the other Sections of the Encyclopedia investigate in detail. To facilitate the detection of these connections, each article proposes, at the end, a suggested “reading map” by indicating the conceptually closer articles in the Encyclopedia (i.e., cross references).

To maximize readers' benefit when using the Encyclopedia, what follows briefly illustrates the planning phase of this Section by discussing the logic adopted in defining the article types and content the Section strived to put together.

When I accepted the invitation to coordinate this section of the Encyclopedia I decided to adopt a potential-reader-perspective and asked myself about the main type of issues/categories somebody reverting to an Encyclopedia might be interested in discovering. After a lengthy period of critical thinking, inspiration taken from other Encyclopedias, conversations with colleagues and friends (e.g., Prof. Valerio Gatta, and Dr. Ila Maltese) and, of course, many changes brought to the original structure, I adopted the following framework that was, at least from my standpoint, useful in defining the type and number of articles to include.

The structure of the section rests on the definition of the most important transport modes, which are the “classical” ones: road, rail, air and maritime.

With the intent of providing a systematic and consistent treatment of each mode, the Section unfolds by adopting a hierarchical structure so to provide a clear perspective and avoid jeopardizing consistency. In more detail, the hierarchy adopted is the following.

Type A papers can be defined generic since they deal with issues from a broad transport modes perspective (e.g., ageing society and transport modes). These papers have a “bridging” nature with respect to other sections in the Encyclopedia.

Type B papers deal with a single transport mode. They set the overall picture of a given mode by introducing the current situation, history, future, geography and its territorial scale.

Type C papers deal specifically with “infrastructure” and “vehicles” with attention paid to both terminals and lines. Whenever appropriate, both for infrastructure and vehicles, the papers investigate: (1) planning, (2) management, (3) regulation, (4) design, (5) manufacturing, and (6) ITS issues.

The full combination of all these aspects would have produced approximately 145 papers that were way above the maximum number of papers allotted to this Section and above the potential number of articles any reader would bear to read just on transport modes. Due to various reasons linked both to the level of detail and availability of potential Authors, some “leaves” of this tree were pruned leaving us with a total of 93 papers in its final version. This is still a large number of papers to read on transport modes. The articles in this Section provide a comprehensive, updated, coherent and well-articulated set of sources on transport modes that will represent a reference point for all those readers that need an introduction to a specific issue and a guidance for additional readings.

I do hope you will enjoy reading the articles (and linking them to others within this Section and across the Encyclopedia) as much as I did enjoy conceiving, commissioning and revising them.

Infrastructure Transport Investments, Economic Growth and Regional Convergence

Introduction	2
Transport Infrastructure Investments and Economic Growth	2
Spatial Spillovers	3
The Impact of Transport Investments on Regional Convergence	4
Conclusions	4
References	5

Introduction

Investments in transport infrastructures may have strong economic effects since better transport infrastructures lead to a greater outlay of public capital and, hence, the higher productivity of private factors, fewer transport costs for firms, and greater accessibility to territories. In this regard, there is an extensive theoretical literature on identifying the multiple causal mechanisms that link transport and economic growth (see [Lakshmanan, 2011](#) for an in-depth review). The main arguments rely on market expansion, cheaper inputs for production, competition, gains from trade, technological changes, agglomeration forces, and processes of innovation and commercialization of new knowledge in spatial clusters. However, the analysis of transport infrastructure investments on regions requires that the effects related to growth be distinguished from those related to the reorganization of economic activity ([Redding and Turner, 2014](#)).

Indeed, we may expect that they will have a positive aggregate economic effect being the magnitude of the impact an empirical question. However, it is less clear whether transport investments contribute to reduce regional disparities. Recent theoretical literature, under the assumption of increasing returns to scale and imperfect competition, have helped to explain, in a common framework, both divergence and convergence processes in a context of a decrease of transportation costs. The main contribution of the so-called theory of the “new economic geography” was that it provided an explanation of the way in which, a priori similar regions, may diverge in their production structures and income levels due to their different access to markets. These location approaches, basically analyzed the ambiguity of the effects on different regions of the reduction of transportation costs ([Puga, 2002](#)). In this regard, the contribution of infrastructure investments—with the consequent effect on the reduction of transport costs—to regional convergence (or divergence) is related to the degree of reduction of such costs and to the conditions of the labor market.

A related issue is the sign and magnitude of the spatial spillovers since it can be expected that investments in transport infrastructures not only have an effect on the territory where they take place but also in nearby areas. Furthermore, we may expect heterogeneous impacts of transport investments according to the concerned mode (roads, rails, ports, and airports) and the characteristics of regions and sectors affected.

In this chapter, we review the empirical literature on the economic effects of transport investments. The rest of this chapter is organized as follows. Section 2 examines the studies that examine the link between transport investments and economic growth. Section 3 analyzes the results in the existing literature on the spatial spillovers of transport investments. Section 4 reviews studies that examine the contribution of transportation to reduce regional disparities. In all cases, we put particular attention on the results obtained for specific transportation modes. Finally, Section 5 provides some final considerations.

Transport Infrastructure Investments and Economic Growth

Several empirical studies have used production functions to examine the impact of infrastructures on economic growth. The geographical unit of analysis has been quite diverse and so studies conducted at the country, regional, and local levels are found. In general, the focus of these studies is to estimate the aggregate impact of the stock of public capital on gross domestic product per capita. Early examples of studies using production functions include [Aschauer \(1989\)](#), [Munnell \(1990\)](#), [García-Milà and McGuire \(1992\)](#), [Holtz-Eakin and Schwartz, \(1995\)](#), and [Fernald \(1999\)](#). Some recent contributions have focused on a case study or a single region study, such as those undertaken by [Cohen \(2010\)](#) or [Berechman et al. \(2006\)](#) for the United States; [Crafts \(2009\)](#) for the United Kingdom; [Fan and Chan-Kang \(2008\)](#), [Lean et al. \(2014\)](#), [Yu et al. \(2012\)](#) for China; [Park and Seo \(2016\)](#) for Korea; [Lall](#)

(2007) for India; Yamaguchi (2007) for Japan; Crescenzi and Rodríguez-Pose (2012) for the European Union, and Farhadi (2015) for the OECD. However, the analysis of comparative data for a large number of countries can be valuable in assessing how transport impacts on the development process in heterogeneous economic contexts (Park et al., 2019).

Given that roads represent a high proportion of the total stock of public capital, studies using production functions typically focus the attention on roads. While it is generally accepted that public capital (above all that related with roads) has positive effects on gross domestic product per capita, the magnitude of these effects is unclear. In general, the impact found is smaller in those studies that use more sophisticated econometric techniques like cointegration models that deal with spurious correlation, instrumental variables models that deal with endogenous biases or models that include time and spatial lags.

In contrast to the extensive literature examining the link between public capital and output, few studies focus on the impact of transport infrastructures on other relevant aspects like costs at the sector level, innovation, location choices of firms, or regional employment. The focus on production functions may be explained by the more widely availability of data. In this regard, a few studies estimate cost functions (Morrison and Schwartz, 1996; Nadiri and Mamuneas, 1994) and the analysis on regional employment concentrates on one specific mode of transportation at the region or city level. While some studies about the impact of road investments on regional employment do not find a strong effect (Clark and Murphy, 1996; Jiwattanakulpaisarn et al., 2010), those works employing sophisticated identification strategies find a relevant effect (Akyelken, 2015; Duranton and Turner, 2012; Möller and Zierer, 2018; Percoco, 2016; Rephann and Isserman, 1994; Xu and Nakajima, 2017). A positive and significant impact of roads in studies that examine the effects on, for example, the location of manufacturing establishments (Holl, 2004), wages (Matas et al., 2013), regional innovation (Agrawal et al., 2017), or population (Duranton, 2016) have also been found.

Regarding the specific impact of high-speed rails, if it can be said to exist, seems to be limited to the urban core and the area around the station (see Givoni, 2006 and Albalade and Bel, 2012 for detailed reviews). In contrast, Donaldson (2018) and Banerjee et al. (2020) find that the extension of the railroad network in India and China, respectively, has had a positive causal effect on income.

The analyses of the impacts of ports and airports have generally focused on the causal link between different indicators of traffic and some measure of regional or urban performance, so that the impact of investments is indirectly measured through their expected positive effects on those indicators of traffic. In this regard, Bottasso et al. (2013) and Ferrari et al. (2010) report that port throughput has a positive impact on employment while that Brueckner (2003), Bel and Fageda (2008), Percoco (2010), Blonigen and Cristea (2015), Bilotkach (2015), or Albalade and Fageda (2016) find evidence of a strong effect of air traffic on knowledge intensive services.

In general, the evidence about the impact of transport infrastructure has focused on the specific effect of one single mode. Thus, only a few studies have compared the role of different types of transport infrastructure together. Along these lines, Melo et al. (2013) conduct a meta-analysis based on a sample of 563 estimates from 33 previous studies. Their results indicate that the impact of transport infrastructure may vary among countries and type of transport mode, tending to be higher for the United States and for roads. Holmgren and Merkel (2017) conducted a meta-analysis to examine the association between transport infrastructure and economic growth based on 776 estimates from previous studies. They found that the economic sectors are affected differently by the investment in modes of transport infrastructure. In particular, roads have a positive impact on manufacturing and construction, while seaports affect the agricultural sector. Park et al. (2019) examine the role of various types of transport infrastructure on the economic growth of OECD and non-OECD countries. The findings show stronger significance of seaports on economic growth than airports and surface transportation modes, particularly in developing countries.

Spatial Spillovers

Given that the spatial spillovers between regions may be especially relevant in the analysis of economic impacts of transport infrastructures, some studies employ spatial econometric techniques. In this regard, the omission of the spatial interactions may lead to substantial biases in the estimated economic impact of transport infrastructure investments (Berechman et al., 2006; Cohen, 2010). The consideration of spatial interdependencies usually reduces the magnitude of the impacts associated to transport investments and may explain that those impacts are smaller when the analysis focuses on regions instead of countries.

The most common approach is to estimate production functions including as covariates spatial lags of the dependent and explanatory variables. Spatial econometric techniques allow examining the direct effects on the areas in which the infrastructure is located and the spillover effects on neighboring regions. To this point, the sign of the impact of a better transport infrastructure endowment in one region on its neighbors is not, a priori, clear. Indeed, improved infrastructure may give rise to a competition effect associated with the agglomeration of activities in the region with better infrastructure and a complementary effect associated with improved access to other regions or international markets.

In contrast to the extensive literature on direct effects of transport investments, few studies analyze their indirect effects. For example, Delgado and Álvarez (2007) and Moreno and López-Bazo (2007) find evidence of negative indirect effects of road investments in Spain. A negative indirect effect of roads is also found in the study of Lo Cascio et al. (2019) for Italy. This latter study and Percoco (2010) find evidence of positive indirect effects of airports for Italy. Results of Yu et al. (2013) for China are not conclusive since the sign and magnitude of the spatial spillovers due to transport investments differ by region.

In most cases, the analysis is made without any prior disaggregation by type of infrastructure. However, some exceptions are studies that compare the role of different transport modes simultaneously. For the case of Spain, Arbués et al. (2015) find that roads positively affect the output of the region in which the infrastructure is located and its neighboring provinces, while the direct effect of seaports is negative. Fageda and González-Aregall (2017) examine the direct, indirect, and total impacts of all transport modes on

industrial employment and find that only ports are able to generate positive total effects, and that motorways generate indirect negative effects. [Chen and Haynes \(2015\)](#) examine the regional impact of public transportation infrastructure (highways, public railways, public transit, and public airports) in the U.S. Northeast Megaregion. The result suggests that transport infrastructure (except public transit) have significant positive impacts on regional economic growth, most of which is from spillover effects.

The Impact of Transport Investments on Regional Convergence

Economic convergence at national or regional level refers to an inverse relationship between the growth rate of income per capita and the starting level of income per capita. Specifically, it is a situation where the gap in output per capita between regions (or countries) tends to decrease over time. Additionally, the literature distinguishes between absolute and conditional convergence. In the absolute convergence specification, the growth rate is explained only by the initial level of per capita income. The conditional convergence specification includes some other variables in order to control for attributes that may produce different steady-state growth rates among regions, including variables about the capital stock in transport infrastructures. In this literature, transport investments contribute to regional convergence if the negative relationship between the growth of income per capita and the starting level of income per capita is stronger when adding the transport infrastructure variables.

Studies that use samples of several countries generally find a positive effect of surface transportation on regional convergence. [Calderón and Chong \(2004\)](#) use country-level data to show that the endowment of roads and railways (in terms of both quantity and quality) are negatively linked with income inequality. [Del Bo and Florio \(2012\)](#) find a positive effect of motorways on regional convergence using data of regions within the European Union. [Lessmann and Seidel \(2017\)](#) use luminosity data to examine the determinants of regional inequality for a sample of countries from all over the world. They find that higher transport costs lead to more regional inequality in large countries.

In contrast, studies that use regional data within a country generally do not find evidence about a positive influence of transport infrastructure on regional convergence. [Rodríguez-Pose et al. \(2012\)](#) show that public investments in transport infrastructure have not contributed to the regional convergence in Greece. [Cosci and Mirra \(2018\)](#) show that motorway investments in Italy have contributed to the reduction of regional disparities in some period but the opening of the Autostrada del Sole has just contributed to the economic growth of the richer regions. Finally, [Fageda and Olivieri \(2019\)](#) measure the direct, indirect, and total impact of roads, railways, ports, and airports, and they find that only roads appear to have a positive impact on regional convergence.

Some works do not explicitly test for regional convergence, but their analyses have implications on the role of transportation in reducing regional disparities. [Costa-Font and Rodríguez-Oreggia \(2005\)](#) find that public investments have only been able to reduce regional inequalities among the richest regions in Mexico. [Pereira and Andraz \(2006\)](#) find that public investments in transportation in Portugal have contributed to a concentration of the activity in Lisbon. [Checherita \(2009\)](#) shows that the regional convergence process in the United States is not explained by the public capital stock in each state. Finally, several studies show the role of roads in promoting processes of suburbanization or decentralization of population and economic activity within an urban area ([Baum-Snow, 2007](#); [Baum-Snow et al., 2017, 2018](#); [García-López et al., 2015](#)) so that they provide relevant results linking transport investments and inequalities within an urban area.

Conclusions

Many studies have examined the role of transport investments on economic growth. However, some gaps in the current knowledge can be mentioned. In this regard, most of studies have focused on one specific country, particularly when the unit of observation is the region or an urban area. Furthermore, most of studies either consider aggregate transport investments or focus on one single mode. Hence, cross-country studies using data at the region level and studies that consider separately all transport modes may provide new insights and may be useful for policy-makers. Indeed, heterogeneous impacts of transport investments according to region attributes and the specific mode considered can be expected and no clear patterns can be inferred from the current literature.

Furthermore, not many studies consider spatial spillovers that are essential to fully understand the broader effects of transport investments. The omission of the spatial spillovers may lead to an overestimation of the positive impacts of transport investments and may hide some perverse effects of the investment, particularly when the investment is not intended to correct clear bottlenecks. A clear shortcoming of the spatial econometric techniques is the difficulties in addressing the simultaneous determination bias. Thus, studies that took into account both spatial interactions and endogeneity biases would represent a technological advance in methodological terms. In fact, evidence is not conclusive even in the sign of the spatial spillovers so that much more work is needed along these lines.

The literature on the contribution of transportation to regional convergence is scarce, and very few studies provide clues about the contribution of each specific mode to such regional convergence process. Hence, more studies about the link between transport investment and regional disparities that disaggregate by modes are needed. Moreover, it is not at all clear that investments in transport infrastructures really reduce regional disparities and this could be explained by the drivers of such investments (efficiency, equity, redistribution, tactical politics, etc.). Thus, studies that provided a bridge between the literature on the contribution of transportation to regional disparities and the literature about the drivers of such investments may be particularly helpful for policy-makers. A final remark is the need of more studies that examined the role of transport investments to reduce (or increase) inequalities within urban areas.

Introduction

We live in an aging society. Across the globe, people are living longer and coupled with a lower birth rate the percentage of older people is increasing in number. Between 2015 and 2050, the proportion of the world's population over 60 years will nearly double from 12% to 22%. By 2020, the number of people aged 60 years and older will outnumber children under 5 years of age. At the moment, this is more pronounced in high-income countries but is also noticeable to a lesser but growing extent in many low- to middle-income countries. It is forecast that by 2050, 80% of older people will be living in low- and middle-income countries (LMIC).

Mobility is important to older people (Schlag et al., 1996) and a lack of mobility is linked to poorer health and well-being, and increases in depression and loneliness (Fonda et al., 2001; Ling and Mannion, 1995). Some mobility does far more good for health than others. Active travel (walking and cycling) is good for older people's physical health. Regular walking or cycling reduces the risk of coronary heart disease, stroke, cancer, obesity, and type 2 diabetes (NICE, 2013), overall reducing the risk of cardiovascular disease by around 30% and all-cause mortality by 20% (Hamer and Chida, 2008). Driving a car has less direct benefits due to it being a rather sedentary activity. Using public transport can have health benefits if there is walking involved in getting to and from bus stops, which is a protective factor in obesity for older people (Webb et al., 2011). Bus use is especially high among older people where there are concessionary (reduced) or free fares, as in the United Kingdom.

Much of the research in the area of older people and mobility has focused on western society. In such countries the motor vehicle dominates mobility. It is the most used form of transport among older people, of which the pattern of car use has been steadily growing over the last 30–40 years for those aged 65 and over. This seems set to continue with the 50–59 year olds being heavy users of cars, who are likely to take this pattern into old age. Why has there been such a growth in car use among older people? There are push factors—western society has become geared around the car, so that planning and urban design forces people to use vehicles for accessing basic healthcare, shops, and services by, for example, placing them on the edge of city or town centers on major trunk roads, highways, or motorways. In addition, the western world is championed by a hypermobile society where people are highly mobile throughout their life, living in different places, moving for jobs or recreation, moving between different communities, and away from family and friends. In later life, older people may want to stay connected to different communities and to family and friends and hence high levels of mobility are needed to achieve this. Older people are more likely to still be working now than in previous generations and hence need mobility to enable them to access workplaces. There are also factors that pull people to car use, the status symbol and desirability of the car, sold to them by manufacturers for years as a symbol of freedom and independence. The convenience and door-to-door element of using a car and that it is there ready to be used at the whim or need of the owner is hard to match in other modes. Consequently, giving up driving in later life is also associated with multiple negative outcomes. Research has shown that giving up driving is related to restricted community participation, reduced well-being, and an increased risk of depression, anxiety, and other health-related problems, including feelings of stress, loneliness and isolation, and also increased mortality (Edwards et al., 2009; Fonda et al., 2001; Ling and Mannion, 1995; Marottoli et al., 2000; Marottoli et al., 1997; Mezuk and

Figure 1 A model of age-friendly transport system (after [Musselwhite, 2016, 2018a](#)).

[Rebok, 2008](#); [Musselwhite and Haddad, 2010, 2018a, 2018b](#); [Musselwhite and Shergold, 2013](#); [Peel et al., 2002](#); [Ragland et al., 2005](#); [Windsor et al. 2007](#); [Ziegler and Schwanen, 2011](#)).

In LMIC, patterns of car ownership are not as straightforward. Although cars make up a growing amount of transport use in LMICs, in almost all countries they are a luxury that most cannot afford. The difference between the rich and the poor and car use is significant, and those from higher incomes are much more likely to own and drive a car than those from a less well-off background ([Monteiro et al., 2004](#)). This difference is not as pronounced in high-income countries.

Are Older People Safe as Drivers?

In the normal aging process, older people face many physiological challenges that may affect their ability to drive. These include cognitive changes resulting in increased difficulty in sustained and selective attention, cognitive overload, and slower processing ([Zanto and Gazzaley, 2014](#)). Medical conditions such as dementia can impact driving safety. However, a diagnosis of dementia is never a sufficient reason to immediately withdraw driving privileges because there are varied presentations and rates of progression. Changes in eyesight, in particular changes in recovery from glare and reduced vision in low light, can hamper driving ability ([Musselwhite, 2017a](#)). Between 15 and 65 years of age, not only does susceptibility to glare increase, the recovery time from glare increases from 2 to 9 s ([Holland, 2001](#)). Research suggests that by the age of 75 years old drivers may require 32 times the brightness than a 25-year old does in order to be able to see effectively. Finally, changes in muscle tone and ability to detect feedback affect mobility ([Musselwhite, 2017a](#)).

On the whole, older people are safe drivers. Statistics suggest there is an increase in collisions involving older people over the age of 75 in most countries. However, studies tend to attribute that to frailty, older people are more likely to be injured or die from collisions that younger people would walk away from and statistics do not include noninjury collisions. Older people do have issues with eyesight, fatigue, and detecting feedback that may result in different injuries. However, testing does not seem to make any difference to the collision rates, both for older drivers or for the population as a whole ([Mitchell, 2018](#); [Siren and Haustein, 2015](#); [Siren and Meng, 2012](#)).

Age-Friendly Transport System

To help the decision-making process and encourage older people out of the car, alternatives need to be improved. [Musselwhite \(2016, 2018a\)](#) offers a model of age-friendly transport, based on an ecological system, with the individual at the center and then covering walking and cycling, followed by public and community transport and surrounded by laws, rules, and strategy ([Fig. 1](#)). The model highlights that in an age-friendly transport system it is important to get the walking right before other forms of transport can be considered, since accessing the walking environment is needed to access public and community transport. Then overarching all of the modes is formalized policy and informal norms and rules that affect how services and infrastructure are provided.

Active Travel

Walking

Walking is the main mode among the aging population in the majority of LMIC, with long journeys often being the norm especially those from lower socioeconomic backgrounds (Prohaska et al., 2012). It is difficult to obtain comparable figures, but data suggest South Africa, Mexico, Thailand, and Russia have especially high levels of walking among their older people. In higher-income countries, population-wide walking is on the decrease including walking undertaken by older people. For example, in the United Kingdom, Germany, and France, walking has decreased by around 9% in the last 25 years (Musselwhite, 2018b). Walking makes up around 9% of all trips for over 65 in the United States. This is largely as a result of car-centric policies, reducing services and shops within walking distances and the growth of the motor vehicle as the default mode of transport. However, in some countries walking is more prevalent among older people. In the Netherlands, walking accounts for 15% of all trips made by people over 65, and in Denmark around 23% of all trips are by foot for those over 65 years of age (Pucher and Buehler, 2008, 2012). These figures have been stable for a number of years. Quality infrastructure, planning for walking and cycling, and cultural norms are generally seen as reasons for this (Pucher and Buehler, 2008, 2012).

It is relatively dangerous for older people to be pedestrians. In the United Kingdom, they make up 20% of the population and around 21% of overall distance traveled on foot, yet account for 41% of road traffic collisions. In Australia, 4 times the number of pedestrians aged 60 years and over were killed, compared to children under 16 years of age representing around 37% of all-aged fatalities. There are higher numbers in LMIC. Data from Britain (DfT, 2019), Australia (Job, 1998), France (Domnes et al., 2014), and the Netherlands (Dijkstra and Bos, 1997) suggest that older people are overrepresented in injuries resulting from incidents where failure to judge vehicle speed is a significant factor, where they look less at traffic and accept significantly smaller gaps in traffic when crossing the street. Looking at the barriers to walking for older people may help reveal where safety improvements can occur. Frailty is an issue here, but moreover the walking environment is not one that is pleasant for older people.

There are a number of known barriers to walking. Significantly in all countries, poorly maintained pavements, for example, that are frequently cracked or damaged can severely inhibit walking (Musselwhite, 2018b; Newton and Ormerod, 2012) and there are difficulties walking and balancing on tactile pavements (Newton and Ormerod, 2012). Poor surfaces, caused by fallen leaves, rain, ice, or snow, for example, can also be a barrier when not cleared (Wennberg, 2009). Older people also need continuous dedicated space for walking, free from clutter and with minimal sharing with other modes, especially cycling (Musselwhite, 2018b). There should be safe and accessible public conveniences and seating (Newton et al., 2010). To enable walking, older people need a dedicated pavement (or sidewalk) that is often absent in rural areas of high-income countries and very likely to be absent in LMIC (Srichuae et al., 2016).

Difficulty in crossing the road is often cited as an issue for older people. Dedicated crossing facilities must be sited to give pedestrians fixed or temporary right of way across roads, especially in areas where older people need them, along their “desire lines.” Again these are less likely in LMIC, leaving crossing dangerous fast roads at the hands of older people. As people age, their walking speed slows up and so ability to cross roads becomes harder. Dedicated time to cross the road should be allowed for older people. Previous research suggests older people cross the road at between 0.7 and 0.9 meters per second (Asher et al., 2012; Newton and Ormerod, 2008), yet crossing times are set for a walking speed of 1.22 meters per second (m/s) in most countries, and this is too fast for older people. Musselwhite (2015) found that 88% of older people could not complete the crossing in this time. In addition, changes in gait as people age means stepping down from the kerb is harder to negotiate. Hence, crossing places need to have minimal drop or better still be at grade with the road. Older people tend to spend more time looking at their step and less time looking at the traffic, compared to younger people, adding to the potential for dangerous crossing maneuvers or a slower crossing pattern that pedestrian crossings must take into account (Avineri et al., 2012).

Dark or poorly lit streets have a negative effect on older people using the street, both in terms of concerns about falling and because of safety fears (Shumway-Cook et al., 2003). Smog is a deterrent for older people to go out walking, especially in LMIC, but also cities in higher-income countries. Cities in India are particularly a no-go area for older people at certain times of high pollution. Wealthier nations can also suffer similar problems; older people can be at risk in Japanese cities and at times European cities (Deguen and Zmirou-Navier, 2010).

Cycling

Typically, in high-income countries, there is a big decrease in cycling for older people. For example, distance cycled per person per year in England was 15 miles for those over the age of 70 compared to 52 miles for 60–69 year olds and 53 miles across all age groups (Musselwhite, 2018a). Although the number of miles cycled per person per year has increased over the last 13 years for 60–69 year olds, this has not occurred for those aged 70 or over years of age (DfT, 2015). However, the amount of cycling in the United Kingdom among the older (and indeed the younger) population is low compared to other northern European countries. For example, cycling accounts for 23% of trips made by older people in the Netherlands, 15% in Denmark, and 9% in Germany, against less than 1% in the United Kingdom (Pucher & Buehler, 2012; DfT, 2019). In LMIC, cycling is much higher. Around 56% of older Chinese men cycle daily (Lee et al., 2012), with similar numbers in Uganda (Hill and Heesch, 2018).

Barriers to cycling include built environment and personal and cultural factors (Musselwhite, 2018b). One of the major factors putting older people off from cycling is road danger, sharing the road with fast moving, and heavy traffic (Pooley et al., 2013). In Denmark and the Netherlands, where there are higher levels of cycling among older people, dedicated cycling infrastructure is typical, allowing people to cycle off road. Often these spaces are for cyclists only; older people also feel vulnerable

sharing spaces where pedestrians might be present and find shared use paths for walking and cycling difficult to navigate (Jones et al., 2016).

Older people are often put off cycling feeling that they are not fit enough (Davies et al., 1997). Again this is something less likely to be felt in countries where cycling across the life course is the norm and people have continued to cycle throughout their life (Jones et al., 2016).

Public and Community Transport

Public Buses
